In the last lecture, we saw several examples of defining language features by definitional translation. This lecture presents two additional examples, discusses the correctness of these translations, and presents continuations.

1 Laziness

We’ve seen semantics for both the call-by-name \(\lambda\)-calculus and the call-by-value \(\lambda\)-calculus. We can translate a call-by-name program into a call-by-value program. In CBV, arguments to functions are evaluated before the function is applied; in CBN, functions are applied as soon as possible. In the translation, we delay the evaluation of arguments by wrapping them in a function. This is called a thunk: wrapping a computation in a function to delay its evaluation.

Since arguments to functions are turned into thunks, when we want to use an argument in a function body, we need to evaluate the thunk. We do so by applying the thunk (which is simply a function); it doesn’t matter what we apply the thunk to, since the thunk’s argument is never used.

\[
\begin{align*}
T[x] &= x (\lambda y. y) \\
T[\lambda x. e] &= \lambda x. T[e] \\
T[e_1 e_2] &= T[e_1] (\lambda z. T[e_2]) \quad \text{z is not a free variable of } e_2
\end{align*}
\]

2 References

We introduce constructs for creating, reading, and updating memory locations, also called references. The resulting language is still a functional language (since functions are first-class values), but expressions can have side-effects, that is, they can modify state.

The syntax is defined as follows.

\[
\begin{align*}
e ::= x \mid \lambda x. e \mid e_0 e_1 \mid \text{ref } e \mid !e \mid e_1 := e_2 \mid \ell \\
v ::= \lambda x. e \mid \ell
\end{align*}
\]

Expression \(\text{ref } e\) creates a new memory location (like a malloc), and sets the initial contents of the location to (the result of) \(e\). The expression \(\text{ref } e\) itself evaluates to a memory location \(\ell\). Think of a location as being like a pointer to a memory address. The expression \(!e\) assumes that \(e\) evaluates to a memory location, and \(!e\) evaluates to the current contents of the memory location. Expression \(e_1 := e_2\) assumes that \(e_1\) evaluates to a memory location \(\ell\), and updates the contents of \(\ell\) with (the result of) \(e_2\). Locations \(\ell\) are not intended to be used directly by a programmer: they are not part of the surface syntax of the language, the syntax that a programmer would write. They are introduced only by the operational semantics.
We define a small-step CBV operational semantics. We use configurations \(\langle \sigma, e \rangle\), where \(e\) is an expression, and \(\sigma\) is a map from locations to values.

\[
E ::= [] | E \ e | v \ E | \text{ref} \ E | !E | E ::= e | v ::= E \quad \text{\(\langle \sigma, e \rangle \rightarrow \langle \sigma', e' \rangle\)}
\]

\[
\beta\text{-reduction} \quad \frac{\langle \sigma, (\lambda x. e) v \rangle \rightarrow \langle \sigma, e[v/x] \rangle}{\langle \sigma, !\ell \rangle \rightarrow \langle \sigma, v \rangle \quad \sigma(\ell) = v}
\]

\[
\text{Alloc} \quad \frac{\langle \sigma, \text{ref} \ v \rangle \rightarrow \langle \sigma[\ell \mapsto \ v], \ell \rangle}{\ell \notin \text{dom}(\sigma)}
\]

\[
\text{Assign} \quad \frac{\langle \sigma, \ell := v \rangle \rightarrow \langle \sigma[\ell \mapsto \ v], \ell \rangle}{\langle \sigma, v \rangle \rightarrow \langle \sigma[\ell \mapsto \ v], \ell \rangle}
\]

References do not add any expressive power to the \(\lambda\)-calculus: it is possible to translate \(\lambda\)-calculus with references to the pure \(\lambda\)-calculus. Intuitively, this is achieved by explicitly representing the store, and threading the store through the evaluation of the program. The details are left as an exercise.

### 3 Adequacy of translation

In each case, we had a semantics defined for both the source and target language. We would like the translation to be correct, that is, to preserve the meaning of source programs.

More precisely, we would like an expression \(e\) in the source language to evaluate to a value \(v\) if and only if the translation of \(e\) evaluates to a value \(v'\) such that \(v'\) is “equal to” \(v\). What exactly it means for \(v'\) to be “equal to” \(v\) will depend on the translation. Sometimes, it will mean that \(v'\) is the translation of \(v\); other times, it will mean that \(v'\) is somehow equivalent to the translation of \(v\). In particular, there are many ways to define equivalences on functions. One way is to say that two functions are equivalent if they agree on the result when applied to any value of a base type (e.g., integers or booleans). The idea is that if two functions disagree when passed a more complex value (say, a function), then we could write a program that uses these functions to produce functions that disagree on values of base types.

There are two criteria for a translation to be adequate: soundness and completeness. For clarity, let’s suppose that \(\text{Exp}_{\text{src}}\) is the set of source language expressions, and that \(\rightarrow_{\text{src}}\) and \(\rightarrow_{\text{trg}}\) are the evaluation relations for the source and target languages respectively. A translation is sound if every target evaluation represents a source evaluation:

**Soundness:** \(\forall e \in \text{Exp}_{\text{src}}. \text{if } \mathcal{T}[e] \rightarrow^*_{\text{trg}} v' \text{ then } \exists v. e \rightarrow^*_{\text{src}} v \text{ and } v' \text{ equivalent to } v\)

A translation is complete if every source evaluation has a target evaluation.

**Completeness:** \(\forall e \in \text{Exp}_{\text{src}}. \text{if } e \rightarrow^*_{\text{src}} v \text{ then } \exists v'. \mathcal{T}[e] \rightarrow^*_{\text{trg}} v' \text{ and } v' \text{ equivalent to } v\)

### 4 Continuations

So far we have seen a number of language features that extend lambda calculus, and have translated many of these into the pure lambda calculus, using a direct semantic translation. That is, the control structure of the source language translated into the corresponding control structure in the target language:

\[
\mathcal{T}[\lambda x. e] = \lambda x. \mathcal{T}[e] \\
\mathcal{T}[e_1 e_2] = \mathcal{T}[e_1] \mathcal{T}[e_2]
\]
This style of translation works well when the source language is similar to the target language. However, when the control structures of the source and target languages differ considerably, it doesn’t work as well.

Continuations are a programming technique that may be used directly by a programmer, or used in program transformations by a compiler. Because they make the control flow of the program explicit, they can be used to overcome discrepancies between source and target languages in definitional translation. They can also be used to define the semantics of control-flow constructs such as exceptions.

Intuitively, a continuation represents “the rest of the program.” Consider the program

\[
\text{if } f o o < 10 \text{ then } 32 + 6 \text{ else } 7 + b a r
\]

and consider the evaluation of the expression \( f o o < 10 \). When we finish evaluating this subexpression, we will evaluate the \text{if} statement, and then evaluate the appropriate branch. The \textit{continuation} of the subexpression \( f o o < 10 \) is the rest of the computation that will occur after we evaluate the subexpression. We can write this continuation as a function that takes the result of the subexpression:

\[
(\lambda y. \text{if } y \text{ then } 32 + 6 \text{ else } 7 + b a r) (f o o < 10)
\]

The evaluation order and result of this program will be the same as the original expression; the difference is that we extracted the continuation of the subexpression in to a function.

The nice thing about continuations is that it makes the control explicit, and this is especially useful in the case of functional programs, where control is not explicit otherwise. In fact, we can rewrite a program to make continuations more explicit. Let’s consider another program, and convert it so that continuations are explicit. Let’s think about the following applied \( \lambda \)-calculus program.

\[
(\lambda x. x) ((1 + 2) + 3) + 4
\]

We’ll start by defining a continuation for the outermost evaluation context, which takes a value, and applies the identity function to it.

\[
k_0 = \lambda v. (\lambda x. x) v
\]

The evaluation context that is evaluated next-to-last takes a value, adds 4 to it, and then passes the result to \( k_0 \).

\[
k_1 = \lambda a. k_0 (a + 4)
\]

Likewise, for the next evaluation contexts.

\[
k_2 = \lambda b. k_1 (b + 3)
k_3 = \lambda c. k_2 (c + 2)
\]

The program itself is now equivalent to \( k_3 1 \). Since \( \text{let } x = e \text{ in } e' \) is just syntactic sugar for \((\lambda x. e') e\), we can actually rewrite the above as

\[
\begin{align*}
&\text{let } c = 1 \text{ in} \\
&\text{let } b = c + 2 \text{ in} \\
&\text{let } a = b + 3 \text{ in} \\
&\text{let } v = a + 4 \text{ in} \\
&(\lambda x. x) v
\end{align*}
\]
This is fairly close to some machine instructions of the form:

```plaintext
set c, 1
add b, c, 2
add a, b, 3
add v, a, 4
call id, v
```

Using continuations, functions can be transformed into “functions that don’t return”—i.e., functions that take, besides the usual arguments, an additional argument representing a continuation. When the function finishes, it invokes the continuation on its result, instead of returning the result to its caller. Writing functions in this way is usually referred to as Continuation-Passing Style, or CPS for short. For instance, the CPS version of factorial looks like the following:

```plaintext
FACT_{cps} = Y f: n; k: if n = 0 then k 1 else f (n - 1) (\lambda v. k (n * v))
```

Note that the last thing that code in FACT_{cps} does is call a function (either k or f), and does not do anything with the result.

Continuation-passing style is an important concept in the compilation of functional languages and is used as an intermediate compiler representation (it has been used in compilers for Scheme, ML, etc). The main advantage is that CPS makes the control flow explicit and makes it easier to translate functional code to machine code where control is explicit (in the form of sequences of machine instructions and jumps). For instance, a CPS call can be easily translated into a jump to the invoked method, since the invoked function does not return the control.

4.1 CPS translation

We can translate \( \lambda \)-calculus programs into continuation-passing style. We define a translation function \( \mathcal{CPS}[\cdot] \), which takes a CBV \( \lambda \)-calculus expression, and translates the expression to a CBV \( \lambda \)-calculus expression in continuation-passing style.

Let’s consider a translation from \( \lambda \)-calculus with pairs and integers. The syntax of the source language is as follows.

```plaintext
e ::= x | \lambda x. e | e_1 e_2 | n | e_1 + e_2 | (e_1, e_2) | \#1 e | \#2 e
```

The translation \( \mathcal{CPS}[e] \) will produce a function that whose argument is the continuation to which to pass the result. That is, for all expressions \( e \), the translation is of the form \( \mathcal{CPS}[e] = \lambda k. \ldots \), where \( k \) is a continuation. We will both assume and guarantee that for any expression \( e \), the translation \( \mathcal{CPS}[e] = \lambda k. \ldots \) will apply \( k \) to the result of evaluating \( e \).

For convenience, instead of writing \( \mathcal{CPS}[e] = \lambda k. \ldots \) we write \( \mathcal{CPS}[e] k = \ldots \).
\[ \text{CPS}[n] \quad k = k \cdot n \]
\[ \text{CPS}[e_1 + e_2] \quad k = \text{CPS}[e_1] \cdot (\lambda n. \text{CPS}[e_2] \cdot (\lambda m. k \cdot (n + m))) \quad n \text{ is not a free variable of } e_2 \]
\[ \text{CPS}[(e_1, e_2)] \quad k = \text{CPS}[e_1] \cdot (\lambda w. \text{CPS}[e_2] \cdot (\lambda v. k \cdot (v, w))) \quad v \text{ is not a free variable of } e_2 \]
\[ \text{CPS}[\#1 e] \quad k = \text{CPS}[e] \cdot (\lambda v. k \cdot (\#1 v)) \]
\[ \text{CPS}[\#2 e] \quad k = \text{CPS}[e] \cdot (\lambda v. k \cdot (\#2 v)) \]

\[ \text{CPS}[x] \quad k = k \cdot x \]
\[ \text{CPS}[\lambda x. e] \quad k = k \cdot (\lambda x, k'. \text{CPS}[e] \cdot k') \quad k' \text{ is not a free variable of } e \]
\[ \text{CPS}[e_1 \cdot e_2] \quad k = \text{CPS}[e_1] \cdot (\lambda f. \text{CPS}[e_2] \cdot (\lambda v. f \cdot v \cdot k)) \quad f \text{ is not a free variable of } e_2 \]

We translate a function \( \lambda x. e \) to a function that takes an additional argument \( k' \), which is the continuation after the function application. That is, \( k' \) is the continuation to which we hand the result of evaluating the function body. In function application, we see that in addition to the actual argument, we also give the continuation as the additional argument.

Let’s see an example translation and execution...

\[ \text{CPS}[(\lambda a. a + 6) \cdot 7] \quad \text{ID} = \text{CPS}[(\lambda a. a + 6)] \cdot (\lambda f. \text{CPS}[7] \cdot (\lambda v. f \cdot v \cdot \text{ID})) \]
\[ = (\lambda f. \text{CPS}[7] \cdot (\lambda v. f \cdot v \cdot \text{ID})) \cdot (\lambda a, k'. \text{CPS}[a + 6] \cdot k') \]
\[ = (\lambda f. (\lambda v. f \cdot v \cdot \text{ID}) \cdot 7) \cdot (\lambda a, k'. \text{CPS}[a + 6] \cdot k') \]
\[ = (\lambda f. (\lambda v. f \cdot v \cdot \text{ID}) \cdot 7) \cdot (\lambda a, k'. \text{CPS}[a] \cdot (\lambda n. \text{CPS}[6] \cdot (\lambda m. k' \cdot (m + n)))) \]
\[ = (\lambda f. (\lambda v. f \cdot v \cdot \text{ID}) \cdot 7) \cdot (\lambda a, k'. \text{CPS}[a] \cdot (\lambda n. (\lambda m. k' \cdot (m + n)) \cdot 6)) \]
\[ = (\lambda f. (\lambda v. f \cdot v \cdot \text{ID}) \cdot 7) \cdot (\lambda a, k'. (\lambda n. (\lambda m. k' \cdot (m + n)) \cdot 6) \cdot a) \cdot v \cdot \text{ID} \cdot 7 \]
\[ = (\lambda a, k'. (\lambda n. (\lambda m. k' \cdot (m + n)) \cdot 6) \cdot a) \cdot 7 \cdot \text{ID} \]
\[ = (\lambda n. (\lambda m. \text{ID} \cdot (m + n)) \cdot 6) \cdot 7 \]
\[ = (\lambda m. \text{ID} \cdot (m + 7)) \cdot 6 \]
\[ = \text{ID} \cdot (6 + 7) \]
\[ = \text{ID} \cdot 13 \]
\[ = 13 \]
