A Problem with Subclasses

```
class Fraction(object):
    """Instances are normal fractions n/d"""
    # INSTANCE ATTRIBUTES
    # _numerator:  int
    # _denominator: int > 0

class BinaryFraction(Fraction):
    """Instances are fractions k/2ⁿ"""
    # INSTANCE ATTRIBUTES same but
    # _denominator: int = 2ⁿ, n ≥ 0

    def __init__(self,k,n):
        """Make fraction k/2ⁿ """
        assert type(n) == int and n >= 0
        super().__init__(k,2 ** n)
```

```
>>> p = Fraction(1,2)
>>> q = BinaryFraction(1,2) # 1/4
>>> r = p*q
```

Python converts to

```
>>> r = p.__mul__(q) # ERROR
```

__mul__ has precondition
type(q) == Fraction

1

The isinstance Function

- isinstance(<obj>,<class>)
  - True if <obj>'s class is same as or a subclass of <class>
  - False otherwise
- **Example**:
  - isinstance(e,Executive) is True
  - isinstance(e,Employee) is True
  - isinstance(e,object) is True
  - isinstance(e,str) is False
- Generally preferable to type
  - Works with base types too!

e   id4

id4

Executive	
_name	'Fred'
_start	2012
_salary	0.0
_bonus	0.0

object

Employee

Executive

2

Fixing Multiplication

```
class Fraction(object):
    """Instances are fractions n/d"""
    # _numerator:  int
    # _denominator: int > 0

    def __mul__(self,q):
        """Returns: Product of self, q
        Makes a new Fraction; does not
        modify contents of self or q
        Precondition: q a Fraction"""
        assert isinstance(q, Fraction)
        top = self.numerator*q.numerator
        bot = self.denominator*q.denominator
        return Fraction(top,bot)
```

```
>>> p = Fraction(1,2)
>>> q = BinaryFraction(1,2) # 1/4
>>> r = p*q
```

Python converts to

```
>>> r = p.__mul__(q) # OKAY
```

Can multiply so long as it
has numerator, denominator

3

Error Types in Python

- All errors are instances of class BaseException
- This allows us to organize them in a hierarchy

```
BaseException
__init__(self,msg)
__str__(self)
...

Exception(BE)

AssError(E)
```

BaseException

↑

Exception

↑

AssertionError

id4

AssertionError	
'My error'	

→ means "extends"
or "is an instance of"

4

Python Error Type Hierarchy

```
            BaseException
           /            \
     SystemExit      Exception
                    /  |  |  |  \
AssertionError AttributeError ArithmeticError IOError TypeError ValueError …
                       |
            ZeroDivisionError OverflowError …
```

Argument has
wrong **type**
(e.g. float([1]))

Argument has
wrong **value**
(e.g. float('a'))

http://docs.python.org/
library/exceptions.html

Why so many error types?

5

Handling Errors by Type

- try-except blocks can be restricted to **specific** errors
  - Doe except if error is **an instance** of that type
  - If error not an instance, do not recover
- **Example**:

```
try:
    val = input()      # get number from user
    x = float(val)     # convert string to float
    print("The next number is '+str(x+1))
except ValueError:
    print('Hey! That is not a number!')
```

May have IOError

May have ValueError

Only recovers ValueError.
Other errors ignored.

6

Creating Errors in Python

- Create errors with `raise`
  - **Usage**: raise `<exp>`
  - `exp` evaluates to an object
  - An instance of Exception
- Tailor your error types
  - **ValueError**: Bad value
  - **TypeError**: Bad type
- Still prefer **asserts** for preconditions, however
  - Compact and easy to read

```
def foo(x):
    assert x < 2, 'My error'
    ...
```

Identical

```
def foo(x):
    if x >= 2:
        m = 'My error'
        err = AssertionError(m)
        raise err
```

7

Creating Your Own Exceptions

```
class CustomError(Exception):
    """An instance is a custom exception"""
    pass
```

This is all you need
  - No extra fields
  - No extra methods
  - No constructors
  Inherit everything

Only issues is choice of parent error class. Use `Exception` if you are unsure what.

8

Handling Errors by Type

- try-except can put the error in a variable
- **Example**:

```
try:
    val = input()        # get number from user
    x = float(val)       # convert string to float
    print('The next number is '+str(x+1))
except ValueError as e:
    print(e.args[0])
    print('Hey! That is not a number!')
```

Some Error subclasses have more attributes

9

Accessing Attributes with Strings

- `hasattr(<obj>,<name>)`
  - Checks if attribute exists
- `getattr(<obj>,<name>)`
  - Reads contents of attribute
- `delattr(<obj>,<name>)`
  - Deletes the given attribute
- `setattr(<obj>,<name>,<val>)`
  - Sets the attribute value
- `<obj>.__dict__`
  - List all attributes of object

id1	
	Point3
x	2.0
y	3.0
z	5.0

Treat object like dictionary

id2	
	dict
'x'	2.0
'y'	3.0
'z'	5.0

10

Typing Philosophy in Python

- **Duck Typing**:
  - "Type" object is determined by its methods and properties
  - Not the same as `type()` value
  - Preferred by Python experts
- Implement with `hasattr()`
  - `hasattr(<object>,<string>)`
  - Returns true if object has an attribute/method of that name
- This has many problems
  - The name tells you nothing about its specification

```
class Fraction(object):
    """Instances are fractions n/d"""
    # _numerator:   int
    # _denominator: int > 0
    ...
    def __eq__(self,q):
        """Returns: True if self, q equal,
        False if not, or q not a Fraction"""
        if (not (hasattr(q,'numerator') and
                hasattr(q,'denominator'))):
            return False
        left = self.numerator*q.denominator
        rght = self.denominator*q.numerator
        return left == rght
```

11

Final Word on Typing

- How to implement/use typing is **controversial**
  - Major focus in **designing new languages**
  - Some langs have no types; others complex types
- Trade-of between **ease-of-use** and **robustness**
  - Complex types allow automated bug finding
  - But make they also make code harder to write
- What we really care about is **specifications**
  - **Duck Typing:** we *think* the value meets a spec
  - Types **guarantee** that a specification is met

12
