Local Search

Readings R&N: Chapter 4:1 and 6:4
So far:

methods that **systematically** explore the search space, possibly using principled pruning (e.g., A*)

Current best such algorithm can handle search spaces of up to $10^{100}$ states / around 500 binary variables ("ballpark" number only!)

What if we have **much larger search spaces**?

Search spaces for some real-world problems may be much larger e.g. $10^{30,000}$ states as in certain reasoning and planning tasks.

A completely different kind of method is called for --- **non-systematic**:

Local search
(sometimes called: Iterative Improvement Methods)
Problem: Place N queens on an N x N chess board so that no queen attacks another.

Example solution for N = 8.

How hard is it to find such solutions? What if N gets larger?

Can be formulated as a search problem.
Start with empty board. [Ops? How many?]
Operators: place queen on location (i,j). [N^2. Goal?]
Goal state: N queens on board. No-one attacks another.

N=8, branching 64. Solution at what depth?
N. Search: (N^2)^N Informed search? Ideas for a heuristic?

Issues: (1) We don’t know much about the goal state. That’s what we are looking for!
(2) Also, we don’t care about path to solution!

What algorithm would you write to solve this?
Local Search: General Principle

Key idea (surprisingly simple):

1) Select (random) initial state (initial guess at solution)
   e.g. guess random placement of N queens

2) Make local modification to improve current state
   e.g. move queen under attack to “less attacked” square

3) Repeat Step 2 until goal state found (or out of time) Unsolvable if out of time?
cycle can be done billions of times

Requirements:

  – generate an initial
    (often random; probably-not-optimal or even valid) guess
  – evaluate quality of guess
  – move to other state (well-defined neighborhood function)

  . . . and do these operations quickly
  . . . and don't save paths followed

Not necessarily!
Method is incomplete.
Local Search

1) Hill-climbing search or greedy local search
2) Simulated annealing
3) Local beam search (not covered)
4) Genetic algorithms (related: genetic programming)
5) Tabu search (not covered)
Hill-climbing search

“Like climbing Everest in thick fog with amnesia”
Keep trying to move to a better “neighbor”, using some quantity to optimize.

```plaintext
function HILL-CLIMBING(problem) returns a state that is a local maximum
inputs: problem, a problem
local variables: current, a node
                neighbor, a node

current ← MAKE-NODE(INITIAL-STATE[problem])
loop do
    neighbor ← a highest-valued successor of current
    if VALUE[neighbor] ≤ VALUE[current] then return STATE[current]
current ← neighbor
```

Note: (1) “successor” normally called neighbor.
(2) minimization, isomorphic.
(3) stops when no improvement but often better to just “keep going”, especially if improvement = 0
4-Queens

States: 4 queens in 4 columns (256 states)
Neighborhood Operators: move queen in column
Evaluation / Optimization function: \( h(n) = \text{number of attacks} / \text{"conflicts"} \)
Goal test: no attacks, i.e., \( h(G) = 0 \)

Initial state (guess).

Local search: Because we only consider local changes to the state at each step. We generally make sure that series of local changes can reach all possible states.
Representation: 8 integer variables giving positions of 8 queens in columns (e.g. <2, 5, 7, 4, 3, 8, 6, 1>)

Section 6.4 R&N (“hill-climbing with min-conflict heuristics”)
Pick initial complete assignment (at random)
Repeat
  • Pick a conflicted variable var (at random)
  • Set the new value of var to minimize the number of conflicts
  • If the new assignment is not conflicting then return it

(Min-conflicts heuristics)  →  Inspired GSAT and Walksat
Local search with min-conflict heuristic works extremely well for N-queen problems. Can do millions and up in seconds. Similarly, for many other problems (planning, scheduling, circuit layout etc.)

**Why?**

Commonly given: Solns. are densely distributed in the $O(n^n)$ space; on average a solution is a few steps away from a randomly picked assignment. But, solutions still exponentially rare!

In fact, density of solutions not very relevant. Even problems with a single solution can be "easy" for local search!

*It all depends on the structure of the search space and the guidance for the local moves provided by the optimization criterion.*

For N-queens, consider $h(\text{state}) = k$, if $k$ queens are attacked.

Does this still give a valid solution? Does it work as well?

What happens if $h(n) = 0$ if no queen under attack; $h(n) = 1$ otherwise? Does this still give a valid solution? Does it work as well? What does search do?

"Blind" local search! Provides no gradient in optimization criterion!
Issues for hill-climbing search

Problem: depending on initial state, can get stuck in local optimum (here maximum)

How to overcome local optima and plateaus?

→ Random-restart hill climbing

But, 1D figure is deceptive. True local optima are surprisingly rare in high-dimensional spaces! There often is an escape to a better state.
Local Optima: No neighbor is better, but not at global optimum.
   - May have to move away from goal to find (best) solution.
   - But again, true local optima are rare in many high-dimensional spaces.

Plateaus: All neighbors look the same.
   - 8-puzzle: perhaps no action will change # of tiles out of place.
   - Soln. just keep moving around! (will often find some improving move eventually)

Ridges: sequence of local maxima

May not know global optimum: Am I done?
Improvements to Greedy / Hill-climbing Search

Issue:
- How to move more quickly to successively better plateaus?
- Avoid “getting stuck” / local maxima?

Idea: Introduce “noise:”

downhill (uphill) moves to escape from plateaus or local maxima (minima)

E.g., make a move that increases the number of attacking pairs.

Noise strategies:

1. Simulated Annealing
   - Kirkpatrick et al. 1982; Metropolis et al. 1953

2. Mixed Random Walk (Satisfiability)
   - Selman, Kautz, and Cohen 1993
Simulated Annealing

Idea:
Use conventional hill-climbing style techniques, but occasionally take a step in a direction other than that in which there is improvement (downhill moves; away from solution).

As time passes, the probability that a down-hill step is taken is gradually reduced and the size of any down-hill step taken is decreased.
Simulated annealing search
(one of the most widely used optimization methods)

Idea: escape local maxima by allowing some "bad" moves but gradually decrease frequency of such moves.

function SIMULATED-ANNEALING(problem, schedule) returns a solution state
inputs: problem, a problem
         schedule, a mapping from time to “temperature”
local variables: current, a node
               next, a node
               T, a “temperature” controlling prob. of downward steps

current ← MAKE-NODE(INITIAL-STATE[problem])
for t ← 1 to ∞ do
   T ← schedule[t]
   if T = 0 then return current
   next ← a randomly selected successor of current
   ΔE ← VALUE[next] − VALUE[current]
   if ΔE > 0 then current ← next
   else current ← next only with probability $e^{ΔE/T}$

Similar to hill climbing, but a random move instead of best move

Since $e^{ΔE/T}$ decreases exponentially with $T$, case of improvement, make the move

Otherwise, choose the move with probability that decreases exponentially with the “badness” of the move.

What’s the probability when: $T \to \infty$?
What’s the probability when: $T \to 0$?
What’s the probability when: $\Delta E = 0$? (sideways / plateau move)
Noise model based on statistical mechanics
– ... introduced as analogue to physical process of growing crystals

Convergence:

1. With exponential schedule, will provably converge to global optimum
   One can prove: If $T$ decreases slowly enough, then simulated annealing search
   will find a global optimum with probability approaching 1

2. Few more precise convergence rate.
   (Recent work on rapidly mixing Markov chains.
   Surprisingly deep foundations.)

Key aspect: downwards / sideways moves
– Expensive, but (if have enough time) can be best

Thousands of papers; original paper one of most cited papers in CS!
– Many applications: VLSI layout, factory scheduling, protein folding. . .
Superficially: SA is local search with some noise added. Noise starts high and is slowly decreased.

True story is much more principled:

\[ SA \text{ is a general sampling strategy to sample from a combinatorial space according to a well-defined probability distribution. } \]

Sampling strategy models the way physical systems, such as gases, sample from their statistical equilibrium distributions. Order \(10^{23}\) particles. Studied in the field of statistical physics.

We will give the core idea using an example.
Example: 3D Hypercube space

Is there a local maximum?

N dimensional “hypercube” space. N =3. $2^3 = 8$ states total.

Goal: Optimize $f(s)$, the value function. Maximum value 4.5 in $s6$.

Use local search: Each state / node has N = 3 neighbors (out of $2^N$ total).
“Hop around to find 101 quickly.”
Of course, real interest in large $N$...

Spaces with $2^N$ states and each state with $N$ neighbors.

7D hypercube; 128 states. Every node, connected to 7 others. Max distance between two nodes: 7.

9D hypercube; 512 states. How many steps to go from any state to any state?

Practical reasoning problem: $N = 1,000,000$. $2^N = 10^{300,000}$
SA node sampling strategy

Consider the following “random walker” in hypercube space:

1) Start at a random node $S$ (the “current node”).
   (How do we generate such a node?)

2) Select, at random, one of the $N$ neighbors of $S$, call it $S'$

3) If $(f(S') - f(S)) > 0$, move to $S'$, i.e. set $S := S'$
   (i.e., jump to node with better value)
   else with probability $e^{(f(S') - f(S))/T}$ move to $S'$, i.e., set $S := S'$

4) Go back to 2)

Note: Walker keeps going and going. Does not get stuck in any one node.
Central Claim --- Equilibrium Distribution:

After “a while,” we will find the walker in state S with probability

\[
\text{Prob}(S) = \frac{e^{(f(S)/T)}}{Z}
\]

where \(Z\) is a normalization constant (function of \(T\)) to make sure the probabilities over all states add up to 1. I.e., we will be in a state with a probability “proportional” to \(f(S)\) --- most likely in state with highest \(f(S)\).

Why? *Deep result in Markov Chain processes. Not obvious at all.*

\(Z\) is called the “partition function” and is given by

\[
Z = \sum e^{(f(s)/T)}
\]

where the sum is over all \(2^N\) states \(x\). So, an exponential sum! Very hard to compute but we generally don’t have to!
Prob(s) = e^(f(s)/T) / Z

<table>
<thead>
<tr>
<th>States</th>
<th>Value f(s)</th>
<th>T=1.0</th>
<th>Prob(s)</th>
</tr>
</thead>

</tbody>
</table>

sum Z = 307.9

So, at T = 1.0, walker will spend roughly 29% of its time in the best state.

T = 0.5, roughly 45% of its time in the best state.

T = 0.25, roughly 65% of its time in the best state.

And, remaining time mostly in s2 (2\textsuperscript{nd} best)!
So, when $T$ gets lowered, the probability distribution starts to **concentrate** on the maximum (and close to maximum) value states.

The lower $T$, the stronger the effect!

What about $T$ high? What is $Z$ and $\text{Prob}(S)$?

At low $T$, we can just output the current state. It will quite likely be a maximum value (or close to it) state. In practice: Keep track of best state seen during the SA search.

SA is an example of so-called Markov Chain Monte Carlo or MCMC sampling.

*It’s very general technique to sample from complex probability distributions by making local moves only. For optimization, we chose a clever probability distribution that concentrates on the optimum states for low $T$. (Kirkpatrick et al. 1984)*
Some final notes on SA:

1) “Claim Equilibrium Distribution” needs proof. Not too difficult but takes a bit of background about Markov Chains. It’s beautiful and useful theory.

2) How long should we run at each $T$? Technically, till the process reaches the stationary distribution. Here’s the catch: may take exponential time in the worst case. But in practice can be remarkably effective.

3) How quickly should we “cool down”? Various schedules in literature.

4) To get (near-)optimum, you generally can run much shorter than needed for full stationary distribution.

5) Keep track of best solution seen so far.

6) A few formal convergence rate results exists, including some polytime results ("rapidly mixing Markov chains").

7) Many variations on basic SA exist, useful for different applications.
Q. Why not just run at a low temperature right away?

SA is guaranteed to converge to the equilibrium distribution
\[ \text{Prob}(s) = \frac{e^{(f(s)/T)}}{Z} \]
However, this can take some time. “Burn-in time of Markov chain.”
Idea of annealing: can reach equilibrium distribution more quickly by first starting at a higher \( T \) and going down slowly.

Practical example: \( T = 100 \), take 100,000 flips. Then, \( T = 0.9 \times 100 = 90 \), take 100,000 flips. Then, \( T = 0.9 \times 90 = 81 \), take 100,000 flips. Etc.

Q. How can you sample properly from an exponential space without the chain first visiting each state?

Best answered with an example. Consider \( N \) binary variables, and starting from the all 0 state (“origin of hypercube”).
How many flips are needed to reach a purely random point uniformly at random in the \( N \) dimensional hypercube?
Genetic Algorithms
Genetic Algorithms

Another class of iterative improvement algorithms

– A genetic algorithm maintains a population of candidate solutions for the problem at hand, and makes it evolve by iteratively applying a set of stochastic operators

Inspired by the biological evolution process
Uses concepts of “Natural Selection” and “Genetic Inheritance” (Darwin 1859)
Originally developed by John Holland (1975)
High-level Algorithm

1. Randomly generate an initial population
2. Evaluate the fitness of members of population
3. Select parents based on fitness, and “reproduce” to get the next generation (using “crossover” and mutations)
4. Replace the old generation with the new generation
5. Repeat step 2 though 4 till iteration N
Stochastic Operators

Cross-over
- decomposes two distinct solutions and then
- randomly mixes their parts to form novel solutions

Mutation
- randomly perturbs a candidate solution
A successor state is generated by combining two parent states.

Start with \( k \) randomly generated states (population).

A state is represented as a string over a finite alphabet (often a string of 0s and 1s).

Evaluation function (fitness function). Higher values for better states.

Produce the next generation of states by selection, crossover, and mutation.
Genetic algorithms

Operate on state representation.

Fitness function: number of non-attacking pairs of queens (min = 0, max = 8 \times 7/2 = 28 \Rightarrow the higher the better)

\[
\frac{24}{24+23+20+11} = 31\%
\]
Genetic algorithms

Any reason pieces from different solutions fit together?
Lots of variants of genetic algorithms with different selection, crossover, and mutation rules.

GAs have a wide application in optimization – e.g., circuit layout and job shop scheduling

Much work remains to be done to formally understand GAs and to identify the conditions under which they perform well.
Demo of Genetic Programming (GP): The Evolutionary Walker

Goal:
Make it run as fast as possible!
Evolve population of control programs.

Stick figure ---
Three nodes:
1 body
2 feet

Basic physics model:
ground
momentum etc.

Discrete time

Actions to control:
1) angle $\alpha$
2) push off ground for each foot.

Input for control program (from physics module):
Position and velocity for the three nodes.

Figure 1.1: The walker model.
Control language:

\[ \begin{align*}
real & := \ real + real \\
& \quad | \ real - real \\
& \quad | \ real \times real \\
& \quad | \ real / real \\
& \quad | \ getX(index) \\
& \quad | \ getY(index) \\
& \quad | \ getX\_velocity(index) \\
& \quad | \ getY\_velocity(index) \\
& \quad | \ if\ (bool)\ then\ real\ else\ real \\
& \quad | \ (constants\ between\ \{-1, 1\}) \\
\\
bool & := \ real < real \\
& \quad | \ real > real \\
& \quad | \ closeTo(real, real) \\
& \quad | \ true \\
& \quad | \ false; \\
\\
index & := 0 \\
& \quad | \ 1 \\
& \quad | \ 2;
\end{align*} \]

Example:

\[
\begin{align*}
& (- \\
& \quad (getX(1)) \\
& \quad \times \\
& \quad (getY\_velocity(2)) \\
& \quad (if\ (getY(0) > 0.319437294) \\
& \quad \quad then\ (getY(2)) \\
& \quad \quad else\ (/\ (getX(2))\ 1.245)))
\end{align*}
\]

Basically, computes a real number to set angle (or push strength) for next time step.

Body and feet will each evolve their own control program.
Population of control programs is maintained and evolved.

Fitness determined by measuring how far the walker gets in $T$ time units ($T$ fixed).

Evolution through parent selection based on fitness. Followed by crossover (swap parts of control programs, i.e., arithmetic expression trees) and mutations (randomly generate new parts of control program).
Can this work? How well?

Would it be hard to program directly? Think about it…

Demo

Summary

Local search algorithms

- Hill-climbing search
- Local beam search (not covered)
- Simulated annealing search
  Equilibrium distribution. Markov chain.
- Genetic algorithms (Genetic algorithms)
- Tabu search (not covered)
1) Surprisingly efficient search technique
2) Often the only feasible approach
3) Wide range of applications
4) Formal properties / guarantees still difficult to obtain
5) Intuitive explanation:
   – Search spaces are too large for systematic search anyway. . .
6) Area will most likely continue to thrive
