

We have seen how to express a few protocols such as mutual exclusion, message acknowledgement, and collecting responses to liveness "pings" in the setting of computation by asynchronous message passing. We also presented an intuitive "theory of events" at a finite number of locations loc_1, \dots, loc_n which send and receive messages. We stressed the idea that there is no global notion of time (no global clock) and that we reason about time in terms of Lamport's notion of causal order among events.

Now we will see how to express these concepts in first-order logic. Unlike the case for first-order number theory where the domain of discourse D is the type of natural numbers, for a theory of events, we need to subdivide the domain into several sorts. We start with the sort of events and locations defined by decidable predicates $E(x)$, $Loc(x)$ on D . For convenience, we also use $Bool(x)$ for Booleans and $Unit(x)$ for a sort with one object written as \bullet ; we also have the natural numbers $N(x)$ when we want them. All of these predicates simply divide D into separate sorts, all disjoint and decidable, i.e. $\forall x.(E(x) \vee \sim E(x))$, $\forall x.(Loc(x) \vee \sim Loc(x))$, $\forall x.(N(x) \vee \sim N(x))$, etc. Later we will see that type theory offers a richer and more flexible way to handle sorts and logic in a uniform way.

Recall the picture of our model of computation. This picture is sometimes called a message sequence diagram.

At each location loc_i events are linearly ordered, creating a sequential notion of time in which events are totally ordered. It does not make sense to draw an arrow going back in time at a location, and causal order proceeds downward as illustrated by the red links from loc_1 to loc_2 to loc_3 to loc_n back to loc_3 back to loc_1 . We show slow processes at a location by the fact that events are widely spaced, not by directing arrows backwards.

We will capture properties of events caused by computational processes executing at each location, so we also think of the locations as processes. These processes could be executing many threads of computation distinguished by the kind of events.

Equality of events

We assume that equality on Locations and Events is decidable, thus $\forall x, y. (E(x) \wedge E(y) \Rightarrow x=y \vee \neg(x=y))$ $\forall x, y. (Loc(x) \wedge Loc(y) \Rightarrow x=y \vee \neg(x=y))$

Notation. It is convenient to write typed quantifiers to express the above concepts as well as many others, e.s. $\forall x, y: E. (x=y \vee \neg(x=y))$ and $\forall x: E. \forall i: Loc. P(x, i)$ means $\forall x, i. (E(x) \wedge Loc(i) \Rightarrow P(x, i))$.

Axiom $\forall x: E. \exists y. (E(y) \vee Loc(y))$

The realizer for this axiom is the term $pred?(x)$, a computable term that defines a function on events whose value is a pair $\langle y, p \rangle$ where y is in the domain D and p is either $in(x)$ or $loc(x)$.^{† footnote.}

Given a particular event e at a location loc_i , the term $pred?(x)$ will decide whether e is the initial event at loc_i and if so, it will return $\langle loc_i, in(x) \rangle$.

Otherwise, $pred?(e)$ will compute to the previous event at the location.

By examining the second component of $\langle y, p \rangle$ we can tell whether the result is an event, e.s. p is $in(x)$, or a location.

If e is not the initial event,

then we can examine the sequence of events at the location of e and find its predecessor. To do this, we need to be able to compute the location of the event.

[†] Footnote: Recall that if $E(y)$ is true, the evidence is $*$, (likewise for $Loc(y)$).

A Theory of Events in FOL

Axiom $\forall x:E. \exists y:Loc. \text{Occurs_at}(x,y)$

The realizer is a term $\text{loc}(x)$ which for any event x computes the unique location of the event. For simplicity we let $\text{loc}(x)$ have value i rather than $\langle i, \# \rangle$. The other option would be to have $\text{locof}(x) = \langle i, \# \rangle$ and $\text{loc}(x) = \text{spread}(\text{locof}(x); i, a. i)$. All events happen at a process/location, and we postulate some unspecified mechanism to find the location. In the formal mathematical model we simply define an event to include its location, e.g. in one formal model from 2003 an event is a pair $\langle i, t \rangle$ where i is the location and t is a discrete time step.

Next we need an axiom for finding the sender of an event. If the event is not a receive, then we associate the unit value rather than the sender.

Axiom $\forall x:E. \exists y.(E(y) \vee \text{Unit}(y))$

The realizer is the term $\text{sender?}(x)$. The term computes by finding the canonical form of the event. If it has the form $\text{rcv}(v)$ then we find the sender from the header or the channel (as with pred?). If x is not a receive, then $\text{sender?}(x)$ computes to the unit value \bullet .

Next we will define $x \triangleleft y$, also written as the binary relation $\text{Pred}(x,y)$. First we define these functions and predicates.

$$\text{first?} : E \rightarrow \text{Bool}$$

$$\begin{aligned} \text{first?}(x) &= \text{spread}(\text{pred?}(x); y, p. \text{decide}(p; l. \text{false}; r. \text{true})) \\ &= \text{let } \text{pred?}(x) = (y, p) \text{ in } \underline{\text{if}} \text{ isl}(p) \underline{\text{then}} \text{false} \\ &\quad \underline{\text{else}} \text{true} \end{aligned}$$

$$\text{sender?} : E \rightarrow E + \text{Unit}$$

$$\begin{aligned} \text{rcv?}(x) &= \text{decide}(\text{sender?}(x); l. \text{true}; r. \text{false}) \\ &= \text{if } \text{isl}(\text{sender?}(x)) \underline{\text{then}} \text{true} \underline{\text{else}} \text{false}. \end{aligned}$$

$$\text{First}(x) \text{ iff } \text{first?}(x) = \text{true}$$

$$\text{Rcv}(x) \text{ iff } \text{rcv?}(x) = \text{true}$$

$$\begin{aligned} \text{Pred}(x,y) \text{ iff } &(\neg \text{First}(y) \ \& \ x = \text{pred}(y)) \\ &\vee (\text{Rcv}(y) \ \& \ x = \text{sender}(y)) \end{aligned}$$

where on y such that $\neg \text{First}(y)$,

$$\text{pred}(y) = \text{spread}(\text{pred?}(y); x, p. x)$$

and on y such that $\text{Rcv}(y)$,

$$\text{sender}(y) = \underline{\text{if}} \text{isl}(\text{sender?}(y)) \underline{\text{then}} \text{outl}(y).$$

We will now form the transitive closure of $\text{Pred}(x,y)$, this will be Lamport's causal order relation, $x < y$. We will be able to prove $\forall x,y: E. (x < y \vee \neg(x < y))$, but we need more axioms.

Given a relation $R(x,y)$ we define its transitive closure as follows. Define $R^{(0)}(x,y)$ iff $R(x,y)$ and $R^{(n+1)}(x,y)$ iff $R(x,z) \& R^{(n)}(z,y)$ for some z .

$$R^*(x,y) \text{ iff } \exists n: \mathbb{N}. R^{(n)}(x,y).$$

Using the notation $x \triangleleft y$ for $\text{Pred}(x,y)$, define

$$x \triangleleft^{(0)} y \text{ iff } x \triangleleft y \text{ and } x \triangleleft^{(n+1)} y \text{ iff } \exists z. (x \triangleleft z \& z \triangleleft^{(n)} y).$$

$$\text{Say } x \triangleleft^* y \text{ iff } \exists n: \mathbb{N}. x \triangleleft^{(n)} y.$$

Definition: Lamport's causal order on events is Pred^* (same as \triangleleft^*).

We will show that we can reason by induction on Pred^* . An elegant way to do this is by postulating that $\text{Pred}(x,y)$ is strongly well founded.

Axiom $\text{Pred}(x,y)$ is strongly well founded, i.e.

$$\exists f: E \rightarrow \mathbb{N}. \forall e, e': E. \text{Pred}(e, e') \Rightarrow f(e) < f(e').$$

We also need an axiom about $\text{pred}(x)$.

Axiom The predecessor function, pred , is injective (i.e. one-to-one).

$$\forall e, e': E. (\text{loc}(e) = \text{loc}(e') \& \neg \text{First}(e) \& \neg \text{First}(e')) \Rightarrow \\ (\text{pred}(e) = \text{pred}(e')) \Rightarrow e = e'$$

Theorem $\text{Pred}^*(x,y)$, causal order, is strongly well founded.
