ABSTRACT
We explore the execution of queries with client-site user-defined functions (UDFs). Many UDFs can only be executed at the client site, for reasons of scalability, security, confidentiality, or availability of resources. How should a query with client-site UDFs be executed? We demonstrate that the standard execution technique for server-site UDFs performs poorly. Instead, we adapt well-known distributed database algorithms and apply them to client-site UDFs. The resulting query execution techniques are implemented in the Cornell Predator database system, and we present performance results to demonstrate their effectiveness. We also consider the question of query optimization in the context of client-site UDFs. The known techniques for expensive UDFs are inadequate because they do not take the location of the UDF into account. We present an extension of traditional System-R optimizers that suitably optimize queries with client-site operations.

Keywords
Distributed Query-Processing, User-Defined-Functions, Client-Site Extensions.

1. INTRODUCTION
Optimization techniques have been studied thoroughly for object-relational SQL queries with expensive user-defined functions (UDFs). The assumptions made in these studies are that (a) the UDF’s cost is known a priori before its location in the plan is determined, (b) the cost is modeled on a per-tuple basis. These assumptions implicitly presume that the user is extending the server with a new function. However, experience with object-relational databases shows that extending the database server is difficult even for experienced programmers, and impossible for large numbers of non-expert users. In large-scale environments like the WWW, users need to incorporate client-site UDFs into SQL queries run at a server. Consider the following motivating example:

A DBMS offers stock market data to its clients over the WWW. The users connect to the database to analyze the performance of companies and to extract the necessary information about prospective candidates for their investments. Sophisticated investors will have their own local collections of analysis algorithms and underlying data that must be integrated into the process of choosing and retrieving the desired information.

Client-site UDFs integrate this user-specific functionality with the DBMS’ query processing. Figure 1 shows an example query that uses such UDFs.

```sql
SELECT S.Name, S.Report
FROM   StockQuotes S
WHERE  S.Change / S.Close >= 0.1 AND
       ClientAnalysis(S.Quotes) > 500
```

Figure 1: Use of a Client-Site UDF

The investor requests names and financial reports of companies that accord to her criteria. The first predicate, filtering companies on a 10%+ uptick, can be expressed with simple SQL predicates and will be executed on the server. However, the second predicate involves a UDF that is executed on the client site.

Such client-site UDFs need to be supported for reasons of confidentiality, security, scalability, and the availability of client-specific resources:

a) The investor's analysis UDFs are valued assets that are ideally not revealed.

b) The UDFs may not be trusted by the server. In earlier work [GMHE98], we showed that the server can trust UDFs written in Java to a certain extent, and we are developing further protection mechanisms [CSM98]. However, the security demands of the server constrain the UDFs. Further, many UDFs are not written in Java, and if these are allowed to run at the server, they could compromise its integrity.

c) In the context of such expensive operations, there is a serious scalability concern, since resource-intensive UDFs of many users would together degrade the server performance.

d) The UDFs may use data that resides exclusively on the client. This data may only be available in a client-
specific representation, or it might represent confidential information.

In our research, the UDFs and their client-site execution environment were implemented in Java. However, there are many other architectural frameworks and distributed implementation models, like CORBA, DCOM, or JavaBeans, that we could have chosen instead, and to which our research results apply.

For the rest of this paper, we will assume that the network connecting the clients with the server forms the bottleneck of client-site UDF execution. This applies for example to clients connected over the Internet, or over an asymmetric connection, where only the downlink has high bandwidth while the uplink will form the bottleneck.

1.1 Summary of Contributions

We believe that client-site UDFs are central to scalable object-relational applications. Existing query processing techniques for expensive UDFs are not appropriate for client-site UDFs. Indeed, the use of traditional approaches leads to slow and inefficient execution. This can be explained by three key observations:

a) Client-site UDF execution time can involve network latency, which needs to be hidden through concurrency.

b) Client-site UDF performance can depend on the optimized usage of network bandwidth. Specifically, the asymmetry between client uplink and downlink needs to factor into query evaluation decisions. It may be possible to trade off bandwidth on the uplink for bandwidth on the downlink.

c) The optimal placement of client-site UDF operators in the query plan is different from the placement of expensive server-site UDFs.

The primary contribution of the paper is the development of techniques to process and optimize queries with client-site UDFs. These techniques blend object-relational query processing with the distributed database algorithms. Specifically, our research makes the following contributions:

1. We develop efficient execution algorithms for client-site UDFs, and describe their implementation.

2. We explore the tradeoffs between algorithms due to asymmetric network connections, and propose options that save bandwidth on the client's uplink at the cost of increased traffic on the downlink.

3. We present a simple cost model that allows us to determine the optimal choice of the execution algorithms and their parameters.

4. We present performance results of the prototype implementation in the Cornell Predator database system.

5. We develop query optimization techniques for complex queries with client-site UDFs. The techniques are extensions of a traditional System-R style optimizer.

Our conclusion is that a database system needs to recognize the special characteristics of client-site UDFs and apply appropriate query evaluation and optimization strategies to such queries.

1.2 Related Work

Our work on queries with client-site UDFs builds on existing work on expensive UDF execution and distributed query processing. The main issues are: (a) how should the UDFs be executed? (b) how should query plans be optimized?

Client-site UDFs are expensive; they cannot simply be treated like built-in, cheap predicates. The existing research on the optimization of queries with expensive server-site functions is closely related. The execution of UDFs is considered straightforward; they are executed one at a time, with caching used to eliminate duplicate invocations. The process of efficient duplicate elimination by caching has been examined in [HN97]. Predicate Migration [HS93, Hel95] determines the optimal interleaving of join operators and expensive predicates on a join tree by using the concept of a rank-order on the expensive predicates. The rank of an operation is determined by its per-tuple cost and its selectivity. The concept was originally developed in the context of join order optimization [IK84, KBZ86, SI92]. The Optimization Algorithm with Rank Ordering [CS97] uses rank order to efficiently integrate predicate placement into a System-R style optimization algorithm. UDF optimization based on rank ordering assumes that the cost of UDF operators is only influenced by the selectivity of the preceding operators. We show in Section 5 that rank order does not apply well to client-site operations. Our optimization algorithm does not rely on it. Another approach models UDF application as a relational join [CGK89, CS93] and uses join optimization techniques. Our approach to optimization takes this route.

There is a wealth of research on distributed join processing algorithms [SA80, ML86] that our work draws upon. The distribution of query processing between client and server has also been proposed independently of client-site UDFs in [FJK96], as a hybrid between data and query shipping. Joins with external data sources, specifically text sources, have been studied in [CDY95]. To avoid the per-tuple invocation overhead of accessing the text source, a semi-join strategy is proposed: Multiple requests are batched in a single conjunctive query and the set of results is joined internally. Earlier work on integration of foreign functions
[CS93] proposes the use of semantic information by the optimizer. Our work is complementary in that semantic information can be used in PREDATOR to transform UDF expressions [Sesh98]. We consider the execution of queries after such transformations have been applied.

To summarize, our work is incremental in that it builds upon existing work in this area. However, the novel aspects of the work are:

(a) We identify client-site UDFs as an important problem and adapt existing approaches to fit the new problem domain.

(b) While earlier work modeled UDFs as joins for the purpose of optimization, we go further by using join algorithms also for the purpose of execution.

(c) We identify and exploit important tradeoffs related to network asymmetry that lead to interesting optimization choices.

2. Client-Site UDF Execution

In this section we explore different execution techniques for a single client-site UDF applied to all the tuples of a relation. For now, we ignore the issue of query optimization and operator placement. In the first subsection, we expose the poor performance of a naive approach that treats client-site UDFs like expensive sever-site UDFs. The next subsection models UDFs as joins, leading to the development of evaluation algorithms that are based on distributed joins.

In our terminology, the input relation consists of argument columns and non-argument columns. Argument columns are columns that are arguments to the UDF, like Quote. Non-argument-columns are for example Report and Name. We call columns that contain the results of the UDF application result columns. The input relation can have two different kinds of duplicates: those which are identical in all columns, called tuple duplicates, and those only identical in the argument columns, called argument duplicates. Simple predicates that rely on the values in the result columns, but can be executed on the client, for example ClientAnalysis(S.Quotes)>500, are called pushable predicates. Similarly, projections that can be applied immediately after the UDF are called pushable projections, as in our example the projection on Report and Name.

2.1 Traditional UDF Execution

Current object-relational databases support server-site UDFs. It is tempting to treat a client-site UDF as a server-site UDF that happens to make an expensive remote function call to the client. If ClientAnalysis were a server-site UDF, the established approach would be to wait for results of each UDF invocation before the next record is processed. This synchronous invocation is based on the assumption that the UDF execution utilizes the system reasonably: Under this assumption, concurrency of multiple invocations would only allow marginal gains. For a client-site UDF, this assumption is wrong because its execution time consists mainly of network latency and client-site processing.

Thus, the encapsulation of the client communication within a generic black-box UDF makes some optimizations impossible. On each call to the UDF, the full latency of network communication with the client is incurred. This is because most iterator-model execution engines do not apply one operator of the query plan pipeline to multiple tuples concurrently. We show the timeline of execution in Figure 2(a).

2.2 UDF Execution

The key observation here is, that even if the client might not process multiple tuples concurrently, the network is capable of accepting further messages while others are already being transferred. This means that we can keep a number of messages concurrently in the pipeline that is formed by downlink, client, and uplink. We refer to this number as the pipeline concurrency factor. Figure 2(b) shows the timeline for a concurrency factor of 5.

Another problem of the traditional approach is the ignorance of network bandwidth. It is possible to vary the bandwidth usage using different execution techniques. Consider the UDF in Figure 1: It seems straightforward to simply send the argument column, Quotes, and receive back the results. Then the selection, ClientAnalysis(S.Quotes)>500, can be applied on the server site. This technique is used for server-site UDFs. But depending on the networking environment the resulting performance might be far from optimal. For example, assume that the client's uplink turns out to be the bottleneck, as is the case with modern communication channels like ADSL, cable modems, and some wireless networks. We might accept additional traffic on the downlink if we could in exchange reduce the load on the...
uplink. We will explore different execution strategies that allow these kinds of tradeoffs.

2.2 UDF Execution as a Join

It is possible to model the UDF application on a table as a join operation. The user-defined function in Figure 1 can be modeled as a virtual table with the following schema:

\[
\text{ClientAnalysis (}
  \text{< PriceQuoteArgument :: TimeSeries,}
  \text{Rating :: Integer >)}
\]

The \text{PriceQuoteArgument} column forms a key, and the only access path is an “indexed” access on this key value. Indexed access in this manner incurs costs independent of the size of the table. UDF execution as a join with such a UDF table, would work analogously to an equi-join with a relation indexed on the join columns.

Since UDF application is modeled as a join, client-site UDF application is accordingly modeled as a multi-site join. We now examine distributed join algorithms as far as they apply to this context.

2.3 Distributed Join Processing

There are three standard distributed algorithms [SA80, ML86] to join an outer relation \( R \) and an inner \( F \), residing on sites \( S(erver) \) and \( C(lient) \):

- **Join at \( S \)**: Send \( F \) to \( S \) and join it there with \( R \). Not feasible for UDFs since the virtual table \( F \) cannot be shipped.
- **Join at \( C \)**: Send \( R \) to \( C \) and join it there with \( F \).
- **Semi-Join**: Send a projection of \( R \) on its join columns to \( C \), which returns all matching tuples of \( F \) to \( S \), where they are joined with \( R \).

Identifying \( S \) with the server and \( C \) with the client, we get two variants for client-site UDF application from the last two options. We will briefly introduce each one now, and go into more detail in the later part of this section.

2.3.1 Semi-Join

Semi-joins are a natural 'set-oriented' extension of the traditional 'tuple-at-a-time' UDF execution strategy. Consider the pseudo code below:

For each batch of tuples in \( R \):

\begin{itemize}
  \item Step 0: Eliminate duplicates
  \item Step 1: Send a batch of unique \( S.x \) values to the client
  \item Step 2: Evaluate UDF(\( S.x \)) for all \( S.x \) values in the batch
  \item Step 3: Send results back to the server
  \item Step 4: Join each result with the corresponding tuples
\end{itemize}

Note that steps 0 through 4 may be executed concurrently because they use different resources. If the batch sent in step 1 consists of only one argument tuple, then this is the 'tuple-at-a-time' approach described in the previous section. If the entire relation \( R \) is sent as a batch we get a classical semi-join. The details of the different steps vary depending on the execution strategy. It is convenient to model this conceptually as below, where the different steps are identified as components of a pipeline, with the potential for pipeline concurrency.

![Figure 3: Semi-Join Architecture](image)

For server-site UDFs, it is considered acceptable if the execution mechanism blocks for each UDF call until the UDF returns the result. However, for client-site UDFs a large part of the over-all execution time for one tuple consists of network latencies -- steps 1 and 3 above. We can ship several tuples on the downlink at the same time while another tuple is processed by the UDF, and several results are being sent back over the uplink. Concurrency between the server, the client, and the network can hide the latencies. To obtain this goal we will architecturally separate the sender of the UDF's arguments from the receiver of its results, and have them and the client work concurrently. These components form a pipeline, whose architecture is shown in Figure 3.

The joining of the UDF results with the processed relation depends on its complexity on the correspondence between the tuple streams received from the client and from the sender. If the sender eliminates duplicates, the receiver has to do an actual join between the two streams. Any join technique (for example, hash-join) is applicable at the receiver. If the sender sorts and groups input on the argument attributes.

2.3.2 Join at the Client

Join at the client site is possible by sending the entire stream of tuples from the outer relation to the client. The UDF is applied to the arguments in each tuple, and the UDF result is added to the tuple and shipped back to the receiver. The sender and the receiver of the tuple streams on the server do not need to coordinate, since the entire tuples (with duplicates) flow through the client. (as shown in Figure 4). Note that this does not necessarily mean that the client makes duplicate UDF invocations: It can cache results, even with support from the server: The server can sort the outgoing stream of tuples on the argument attributes.
An advantage of the client-site join is that pushable selections and projections can be moved to the client site. This reduces the bandwidth used on the client-server uplink. On the other hand, we have to send back the full records minus applicable projections, and not just results, as for the semi-join. Considering non-argument columns, more data is also sent on the downlink. Further, on both downlink and uplink, the semijoin method eliminates argument duplicates, whereas the client-site join performs no duplicate elimination.

![Tradeoffs between Client-Site Join and Semi-Join](image)

The difference between semi-join and client-site join is visualized in Figure 5. The upper graphic shows what is being sent by each join method; the lower one shows what is being returned. The horizontals correspond to the transferred columns while the verticals correspond to rows. We will quantify and experimentally evaluate these tradeoffs in the next section.

### 3. Implementation

We have implemented relational operators that execute client-site UDFs in the Cornell PREDATOR ORDBMS. All server components were implemented in C++ and all client-site components are written in Java. Three different execution strategies can be used:

- Naive tuple-at-a-time execution
- Semi-join
- Client-site join

We first describe the implementation of the algorithms, and then compare their performance. Our goals for the performance evaluation are:

- Demonstrate the problems of the naive evaluation strategy.
- Show the tradeoffs between semi-join and client-site join evaluation of the UDF.

#### 3.1 Join Implementation

We will first describe the semi-join implementation, then discuss how we control concurrency to evaluate the naive approach, and finally, we discuss the client-site join.

##### 3.1.1 Semi-Join

This relational operator implements the semi-join of a server-site table with the non-materialized UDF table on the client site. In our architecture (see Figure 3), the server side consists of three components: the sender, the receiver, and the buffer, with which both communicate records. The sender gets the input records from the child operators and, after sending off the argument columns, enqueues them on the buffer. The receiver dequeues the records from the buffer and then attempts to receive the corresponding results from the client. Sender and receiver are implemented as threads, running concurrently. The buffer as a shared data structure is needed to keep the full records, while only the arguments are sent to the client. Also, records whose argument columns form duplicates of earlier records have to be joined with cached results at the receiver.

##### 3.1.2 Concurrency

The size of the buffer that holds records that are between sender and receiver corresponds to the pipeline concurrency factor: The number of tuples that are on the network or the client concurrently. A concurrency factor of 1 corresponds to one-tuple-at-a-time evaluation.

How large should the concurrency factor be? Analytically, we would expect that the number of records between sender and receiver should be at least the number of records that can be processed by the pipeline sender - client - receiver in the time that it takes for one tuple to pass through this pipeline. Let B be the bandwidth of the pipeline: the minimum of the bandwidths of the downlink, the client UDF processor, and the uplink. Let T be the execution time of the pipeline: the time that it takes for one argument to travel to the client, for the result to be computed, and to be
returned to the server. The number of records that can be processed in this time is simply \( B \times T \) – the pipeline concurrency factor that saturates the pipeline.

### 3.1.3 Client-Site Join

The client-site join uses a variation of this architecture: The sender dispatches the whole records to the client, which sends back the records with the additional argument column. We have the same components as above, but without the buffer between sender and receiver. The client-site join does not require any synchronization between both components, in contrast to the semi-join, where the buffer is used to synchronize sender and receiver. Prototype mechanisms allow the server to specify the argument columns and some simple pushable projections and selections to the client.

### 3.2 Cost Model

We show in the performance evaluation section that the network latency problems of tuple-at-a-time UDF execution can be solved through concurrency (either semi-join or client-site join). Consequently, we focus in our cost-model on these two smarter algorithms. Both algorithms incur nearly identical costs at the client and on the server. We assume that neither client nor server is the pipeline bottleneck, and propose a simple cost model based on network bandwidth. We do recognize that this is a simplification and that a mixture of server, client and network costs may be more appropriate in certain environments (as was shown for distributed databases [ML86]). We also ignore the possibly significant cost of server-site duplicate elimination because the issues are well understood [HN97] and not central to the algorithms that we propose.

#### 3.2.1 Cost Model for Semi-Join and Client-Site Join

We now analyze and empirically evaluate the involved tradeoffs with respect to the factors that were visualized in Figure 5. To quantify the amount of data sent across the network, we define the following parameters:

- **A**: Size of the argument columns / Total size of the input records
- **D**: Number of different argument tuples / Cardinality of the input relation
- **S**: Selectivity of the pushable predicates
- **P**: Size of output record after pushable projections / Size of output record before
- **I**: Size of one input record
- **R**: Size of one UDF result
- **N**: Asymmetry of the network: (bandwidth of the downlink / bandwidth of the uplink.)

On a per-tuple basis, a semi-join will send the (duplicate free) argument columns:

\[ D \times (A \times I) \text{ (semi-join, data on downlink, per record)} \]

The client will return the results without applying any selections or projections:

\[ N \times D \times R \text{ (semi-join, data on uplink, per record)} \]

The client-site join will send the full input records, without eliminating duplicates:

\[ I \text{ (client-site join, data on downlink, per record)} \]

The client will return the received records, together with the UDF results, after applying pushable projections and selections:

\[ N \times (I+R) \times P \times S \text{ (client-site join, data on uplink, per record)} \]

The bandwidth cost incurred at the bottleneck link is the maximum of the costs incurred at each link. \( N \), the network asymmetry weights these costs in the direct comparison. The link with maximum cost will be the link whose used bandwidth is closer to its capacity and who will thus determine the turnaround for the join execution.

### 4. Performance Measurements

We present the results of four experiments: First, we demonstrate the problems of the naive approach by measuring the influence of the pipeline concurrency factor. The next two experiments show the tradeoffs between semi-join and client-site join on a symmetric and an asymmetric network. Finally we show these tradeoffs in their dependence on the size of the returned results for different selectivities.

Our results show that client-site joins are superior to semi-joins for a significant part of the space of UDF applications. Performance improvements are derived by exploiting the tradeoffs between both join methods, especially in the context of asymmetric networks.

All of our experiments were executed with the server running on a 300Mhz Pentium PC with 130 Mbytes of memory. The client ran as a Java program on a 150Mhz Pentium PC with 80 Mbytes of memory, connected over a 28.8KBit phone connection. The asymmetric network was modeled on a 10Mbit Ethernet connection by returning \( N \) times as many bytes as actually stated.

#### 4.1 Concurrency

We evaluated the effect of the concurrency factor on performance for the following simple query:
SELECT UDF(R.DataObject) FROM Relation R

Relation is a table of 100 DataObjects, each of the same size. UDF is a simple function that returned another object of the same size.

Figure 6 gives the overall execution time of the query in seconds, plotted against the concurrency factor (number of records in the downlink-client-uplink pipeline) on the x-axis, for object sizes 100, 500, and 1000 bytes.

Our analysis suggested that the optimal concurrency factor is bandwidth times latency: the number of tuples that can be processed concurrently while one tuple travels through the whole pipeline. Following our assumption, the network is the bottleneck and its bandwidth limits the overall throughput. In this graph, we can observe that the optimal level for 1000 bytes is reached at 5 and for 500 bytes at 10: This would correspond to 5000 bytes as the product of bandwidth and latency. Presumably, for 100 byte object, the optimal concurrency level would be 50.

The presented data were determined with a non-threaded implementation of the presented architecture: This facilitates the simple manipulation of the concurrency factor. All further experiments ran on an implementation that simply uses different threads for sender and receiver. Running these as separate threads naturally saturates the pipeline between them.

4.2 Client-Site Join and Semi-Join on a Symmetric Network

Our analysis suggests that the uplink bandwidth required by the client-site join is linear in the selectivity while the downlink bandwidth is independent of the selectivity. For the total execution time, this means that as long as the downlink is the bottleneck, selectivity will have no effect, but when the uplink becomes the bottleneck, the execution time will increase linearly with selectivity. The semi-join is not affected by a change in selectivity.

SELECT R.Argument, R.NonArgument, UDF2(R.Argument) FROM Relation R WHERE UDF1(R.Argument)

Figure 7: Measured Query

In Figure 8, we plot the overall execution time of the client-site join relative to that of the semi-join against the selectivity of UDF1 on the x-axis. Thus, the line at y = 1.0 represents the execution time of the semi-join. We varied the selectivity from 0 to 1.0 and plot curves for result sizes 100, 1000, 2000, and 5000 bytes. The execution time of a semi-join is independent of the selectivity because semi-joins do not apply predicates early on the client. Thus all client-site join execution time values of one curve are given relative to the same constant. In this, as in all other experiments, we set D=1.

We measured the overall execution time for the query in Figure 7. Relation has 100 rows, each consisting of two data objects, together of size 1000 bytes. A was fixed at 50%: The Argument and the NonArgument object were each 500 bytes. The projection factor, P, is adjusted to the result size, such that: \( P*(I+R) = I*(1-A)+R \), meaning that no arguments have to be returned by the client-site join, only the non-argument columns and the results. UDF1 takes an object from the Argument column and returns true or false, while UDF2 takes the same object and returns a result of known size.

SELECT R.Argument, R.NonArgument, UDF2(R.Argument) FROM Relation R WHERE UDF1(R.Argument)

Figure 8: Client-Site Join versus Semi-Join on a Symmetric Network

We will first discuss the shape of each curve, meaning the slope of the different linear parts, and then its height. It can be observed that for each result size the curve runs flat up to a certain point and from then on rises linearly. For the flat part of the curve the downlink is the bottleneck of the client-site join’s execution. Only from a certain selectivity on will its uplink form the bottleneck and thus determine the shape of the curve. For result size 1000 bytes, this point is at selectivity 0.6, when the returned data volume (S *
(P*(I+R)) = 0.6 * 1500) approaches the received data volume (I = 1000). The larger the result size, the earlier this point will be reached because the ratio of received to returned data changes in favor of the latter. The received data are independent of the selectivities: As long as the downlink dominates, the curve is constant. The increasing, right part of the curves is part of a linear function going through the origin of the graphs: At zero selectivity the uplink would incur no cost. Its cost is linear in the amount of data sent on it, which is linear in the selectivity of the predicate.

The flatness of the left part of each curve is caused by the dominance of the downlink for such selectivities. Savings on the uplink cannot lower the execution time any more. The height of the flat part of the curve reflects the relative execution time of the semi-join. With larger result sizes the left part of the curve will run deeper, because of the relatively higher costs of the uplink-dominated semi-join, compared to the downlink-dominated client-site join. For example, the curve for 2000 goes flat at 0.5 (1000 bytes on semi-join downlink / 2000 bytes on client-site join uplink).

4.3 Client-Site Join and Semi-Join on an Asymmetric Network

In this experiment, we explored the same tradeoffs as above in a changed setting: The network is asymmetric with the downlink bandwidth being hundred times as much as that of the uplink (N=100). This choice was motivated by assuming a 10Mbit cable connection as a downlink that is multiplexed among a group of cable customers. With a 28.8Kbit uplink this would result in N = 350 for exclusive cable access and, as a rough estimate, N = 100 after multiplexing the 10Mbit cable.

![Figure 9: Client-Site Join versus Semi-Join on Asymmetric Network](image)

The same query as above is executed (Figure 7). The argument columns consist of 4000 bytes and the non-argument columns of 1000 (A=80%), and again, only the non-argument columns and the results are returned after the pushable projections (P*(I+R)=I*(1-A)+R). The selectivity is varied along the x-axis from 0 to 1 and we give curves for result sizes 500, 1000, and 5000 bytes. The relative execution time of the client-site join with respect to the semi-join is given in Figure 9.

As our cost model predicts, the bandwidth of the uplink depends linearly on the selectivity. The flat part of the curves in the last graph is absent because the downlink never forms a bottleneck. Our model predicts a selectivity of less than: I/(N*(I+R)*P) = 0.0083 to make the downlink the bottleneck of the lowest curve (result size 5000 bytes).

4.4 Influence of the Result Size

Finally, we fixed the selectivity S and varied the result size R along the x-axis from 0 to 2000 bytes. Four different curves are shown, for selectivities 25%, 50%, 75%, and 100%. The argument size was 100 bytes; the overall input size 500 bytes. Again, only non-arguments and results are returned and, as in the second experiment, the network is symmetric. The resulting execution times of the client-site join relative to those of the semi-join are presented in Figure 10.

![Figure 10: Influence of the Result Size](image)

It can be seen that the client-site join will only be cheaper if the pushable predicates are selective enough to reduce the uplink stream sufficiently and if the results are large enough to realize the gain in comparison to the records that have to be shipped on the downlink. The steep initial decline of the curve represents the change from a downlink bottleneck to an uplink bottleneck. While the former is disadvantageous for the client-site join, the latter emphasizes the role of pushed down predicates and projections. The crossing points of the curves with the 1.0 line satisfies, as expected, that the client-site join’s returned data times the selectivity are equal to the semi-join’s returned data. The curve for selectivity 1.0 will never cross that line. The curves
asymptotically approach the horizontal lines that correspond to their selectivity.

5. Query Optimization

We showed that existing UDF execution algorithms are inadequate for client-site UDF queries and we proposed alternatives. Now we show that existing query optimization techniques are also inadequate. There are two reasons for this:

(a) Multiple client-site operations can exhibit interactions that affect their cost. Even for plans with a single client-site UDF these interactions are relevant, because the result operator of every plan, which ships the results to the client, should modeled like a client-site “output” UDF.

(b) The cost of the client-site join is sensitive to the number of duplicates in its input stream.

The existing approaches rely on the concept of a rank order: Every operation has a rank, defined as its cost per tuple divided over one minus its selectivity. Unless otherwise constrained, expensive operations appear in the plan ordered by ascending rank. The validity of rank-order optimization algorithms is based on two assumptions that are violated by client-site UDFs:

a) The per-tuple execution cost of an operation is known a priori, independent of its position in the query plan.

b) The total execution cost of an operation is its per-tuple cost times the size of the input after duplicate removal. UDFs can be pulled up over a join, without suffering additional invocations on duplicates in the argument columns.

Neither assumption is valid for network-intensive client-site UDFs. The cost of a client-site operation is strongly dependent on its location next to other such operations with which it can be combined. And client-site joins as well as combinations of semi-joins are dependent on the number of duplicates.

We propose an extension of the standard System-R optimization algorithm for such queries. As a running example, we will use the query in Figure 11. A client tries to find cases in which his analysis results in the same rating than that of a broker. Ratings contains the ratings of many companies' stocks by several brokers.

```
SELECT S.Name, E.BrokerName
FROM StockQuotes S, Estimations E
WHERE S.Name = E.CompanyName AND
      ClientAnalysis(S.Quotes)=E.Rating
```

Figure 11: Example Query : Placement of Client-Site UDF

5.1 UDF Interactions

It is important to observe that the execution costs of a client-site UDF depend on the operations executed before and after it. If a client-site operation’s input is produced by another client-site operation, the intermediate result does not have to be shipped back to the server. If such operations share arguments, they can be executed on the client as a group and the arguments are shipped only once. For example, a client-site UDF that is executed immediately before the result operator can be executed together with it, without ever shipping back its results. We will first discuss the case of client-site joins, then that of semi-joins.

5.1.1 Client-Site Join Interactions

Consider our example from Figure 11: There are only two possible orderings of the operators, one executing the client-site function before the join, one after it. In the latter case there are three different options. We describe all four plans in more detail and give possible motivations:

a) **UDF before the join:** The result of the UDF can be used during the join, for example, to use an index on Rating. This also avoids duplicates that the join might generate.

b) **UDF after the join:** The number of tuples and/or the number of distinct argument tuples in the relation might be reduced by the join.

c) **UDF and pushable operations after join:** If the UDF uses the client-site-join algorithm, the selection can be pushed down to the client site, reducing the size of the result stream. Further, projections may also be pushed to the client. In this example, only Name and BrokerName of the selected records are returned to the server.

d) **UDF combined with result delivery:** For many queries, the results need to be delivered to the client. Since there is no other server-site operation between the UDF and the final result operator, the UDF with the pushable operations can be executed in combination with the final operator. This avoids the costs of returning intermediate results from the client and also the costs of shipping the final results.

It can be seen that the locations of UDFs in the query plan (a vs. b) determines the available options for communication cost optimizations: The cost of a UDF application is dependent on the operators before and after it! These locations and the locations of pushable predicates need special consideration during plan optimization. Similar observations can be made about semi-joins, which we consider in the following section.

5.1.2 Semi-Join Interactions

Semi-joins differ from client-site joins in their interactions: Neither the final result operator, nor pushable selections or
projections are relevant for grouping. There are three motivations for grouping semi-joins:

- The result of one client-site UDF is input to another. This avoids sending the results back on the uplink and transferring them, with the other arguments of the second UDF, on the downlink. The upset of the arguments is sent to the first and only duplicates on this superset are eliminated.
- The arguments of one function are a subset of the arguments of another. This saves the costs of sending the subset twice, but implies transferring all duplicates that are not also duplicates in all of the superset's columns.
- The argument column sets of two functions intersect. In this case it can be that we save communication costs when sending the superset instead of the two subsets. We avoid sending columns repeatedly, but we also have to consider the cost of sending the duplicates on each subset that are not duplicates on the whole superset.

As an example, consider the query in Figure 11 with an additional expression in the select clause: \( \text{Volatility}(S.\text{Quotes}, S.\text{FuturePrices}) \). The client requests an estimation of the price volatility for the company stocks selected in the query, as computed by the client-site UDF.

The first two options are extensions of client-site join option (a), while the last two are extensions of (b) and (c):

- a) \( \text{Volatility} \) is pushed down to the location of \( \text{ClientAnalysis} \), so that both can be executed together: The columns \( \text{Quotes} \) and \( \text{Futures} \) are shipped once for both UDFs. This saves shipping \( \text{Quotes} \) twice, but it does not allow the elimination of all duplicates in this column. Identical quotes that are paired with different futures objects have to be shipped several times. In this plan, \( \text{ClientAnalysis} \) does not benefit from the join's selectivity, \( \text{Volatility} \) waives both the join's and the selection's selectivities.
- b) \( \text{ClientAnalysis} \) is executed before the join, for example, because its result is used for index access to \( \text{Estimates} \). \( \text{Volatility} \) is executed after the last selection, to benefit from combined selectivity. It is not joined with the result operator as a client-site join because then its arguments would have to be sent with duplicates.
- c) If \( \text{ClientAnalysis} \) is moved after the join, it can be executed together with \( \text{Volatility} \). Both benefit from the join's selectivity, while the duplicates generated by the join in both needed input columns can be eliminated. Again, the input of \( \text{ClientAnalysis} \) might involve some duplicates.
- d) To avoid all duplicates on \( \text{Quotes} \), \( \text{ClientAnalysis} \) is executed separately, with the selection pushed down. \( \text{Volatility} \) is also not merged with the result operator, to avoid duplicates in its input columns.

5.2 Optimization Algorithm

We start by presenting the basics of System-R style optimization with standard extensions for expensive server-site UDFs. Then we present our modifications for dealing with client-site UDFs using client-site joins and semi-joins.

5.2.1 System-R Optimizer

System R [S+79] uses a bottom-up strategy to optimize a query involving the join of N relations. Three basic observations influence the algorithm:

- Joins are commutative
- Joins are associative
- The result of a join does not depend on the algorithm used to compute it.

Consequently, dynamic programming techniques may be applied.

Initially, the algorithm determines the cheapest plans that access each of the individual relations. In the next step, the algorithm examines all possible joins of two relations and finds the cheapest evaluation plan for each pair. In the next step, it finds the cheapest evaluation plans for each three-relation join. With each step, the sizes of the constructed plans grow, until finally we have the cheapest plan for a join of N relations. At each step, the results from the previous steps are utilized.

This last of the above three observations is not totally justified, because the physical properties of the result of a join can affect the cost of some subsequent joins (thereby violating the dynamic programming assumptions that allow expensive plans to be pruned). The System R optimizer deals with this by maintaining the cheapest plan for every possibly useful interesting property, thereby growing the search space.

5.2.2 Client-Site Join Optimization

We aim at defining an optimization algorithm that can handle queries with client-site UDFs. Our strategy is to treat client-site UDFs in the same way as join operators in the System R optimization algorithm. A comparable approach has been followed in the case of expensive UDFs [CGK89], but for client-site operations we also have to consider the physical location of operations (like [FJK96][SA80]).

Our running example will be the construction of the optimal plan for the query in Figure 11, as executed by our
optimization algorithm. The steps of the algorithm are shown as horizontal layers in Figure 12.

We introduce a new bi-valued physical property, a plan's site, indicating the location of its result. In a server-site plan (cornered boxes), the last applied operation is executed on the server and thus the result is located on the server. In a client-site plan (round boxes), the result is located on the client. As an example for a client-site plan, take the plan that applies ClientAnalysis on relation S, resulting in a relation residing on the client. Joining S with E forms a server-site plan because the result of the join resides on the server.

Figure 12: Client-Site Join Optimization of the Query in Figure 11

When applying the next operation to a plan, the optimizer has to determine the communication costs with respect to the plan's site. A join (performed on the server) applied on a client-site plan requires that the records are shipped from the client to the server, while a client-site function applied on a server-site plan requires the opposite. Take the application of the final result operator to the right plan in step 3: it will not incur any additional communication costs because the relation already resides on the client.

A client-site UDF is executed by a join with a given inner table – the virtual UDF table. To unify our handling of virtual and real joins we consider joins as operations with a given inner table. Every relation in the query introduces such a join operator. In our example we have to consider three operations: the join with S, the join with E, and the client-site join with ClientAnalysis. The application of a real join to a yet empty plan simply results in the base relation of that join. A virtual join cannot be applied to an empty plan.

5.2.3 Semi-Join Optimization

For the semi-join UDF optimization we need to capture the fact that the results of plans after a semi-join are distributed between client and server. To do so, we introduce locations for each column of the intermediate results as physical properties. As an example consider again the plans for the query of Figure 11, extended with Volatility(S.Quotes, S.FuturePrices) in the select clause. We show part of the optimization process in Figure 13, omitting all plans that do not start with the join of S and E.

The initial plan, S⊗E, can be extended by applying either ClientAnalysis or Volatility. Each client-site UDF can deliver its result column and its argument columns on the client site, available for any further operation. If Volatility is applied first, ClientAnalysis can follow without shipping its arguments because its arguments are already on the client. The application of Volatility after ClientAnalysis, on the left side of the tree, cannot use the Quotes column on the client: Duplicates were eliminated on it that were originally paired with different FuturePrices values. Everything has to be shipped back to the server before the adequate columns can be transferred. Similarly, server-site operations, like the selection, always ship everything back to the server before their execution.

Figure 13: Semi-Join Optimization for the Query in Figure 11

5.2.4 Features of the Optimization Algorithm

The key characteristics of the optimization algorithm are:

- For query nodes that apply client-site UDFs, additional physical properties are introduced: the location of the optimized subplan's result, and the subset of its columns that resides on the client
- The number of joins in the plan is $2^{(#joins+#c.s.udfs)}$, that is, the algorithm is exponential in the number of real joins plus the number of client-site UDFs.
- Simple, pushable selections and projections are not modeled as operations, although they are, where possible, pushed to the client.
Grouping of client-site operations, motivated by shared arguments or by result dependencies, is integrated in a uniform way, using the location property.

6. Conclusions
Client-site query extensions (UDFs) will play an increasingly important role in extensible database systems due to scalability, confidentiality, and security issues. We demonstrate that existing UDF evaluation and optimization algorithms are inappropriate for client-side UDFs. We present more efficient evaluation algorithms, and we study their performance tradeoffs through implementation in the Cornell PREDATOR database system. We also present a query optimization algorithm that handles the client-site UDFs appropriately and finds an efficient query plan.
