## Abstract

*We describe a methodology for detecting user errors in spreadsheets, using the notion of units as our basic elements of checking. We define the concept of a header and discuss two types of relationships between headers, namely is-a and has-a relationships. With these, we develop a set of rules to assign units to cells in the spreadsheet. We check for errors by ensuring that every cell has a well-formed unit. We describe an implementation of the system that allows the user to check Microsoft Excel spreadsheets.*

## 1 Introduction

A spreadsheet is a program. That is, not only is the utility—such as VisiCalc [1] or Microsoft Excel [10]—that creates the spreadsheet a program, but so are the individual spreadsheets that we use the utility to implement. Even the humblest spreadsheet user writes simple formulas to compute results and maintain consistency between groups of data. These formulae are user programs.

Not only are spreadsheets programs, they are increasingly one of our most popular programming languages. Millions of users employ spreadsheet utilities on a regular basis. The wealth of features and tools in these utilities lets users perform several complex operations ranging from “what if” calculations to limited forms of database management. Because of their powerful operators, they are used not only in business applications [3], but in some forms of mathematical and scientific computing, both to teach students [7] and to build applications [15].

The widespread use of spreadsheet utilities has an unfortunate consequence: Many users have relatively little formal education in computing. Many of them learn to use spreadsheet utilities primarily by trial-and-error, by copying spreadsheets and formulae from oth-

ers, and so on. Consequently, they are not trained to recognize common programming errors, and may thus fail to spot mistakes. Sociologically, it is also possible that some are more prone to trust the output of a program because it is “from the computer”, not fully realizing the ways in which their actions can corrupt that output.

Unfortunately, spreadsheet utilities are often quite poor at detecting and reporting errors in user spreadsheets. There are many possible reasons for this: the desire to minimize confusing output; the expectation that spreadsheets will remain modest, not grow into large programs; and the difficulty in identifying errors and reporting them meaningfully. Sadly, this lack of checking means a great number of spreadsheets are actually buggy [11]. As spreadsheet programs grow, and business decisions and workflows increasingly rely on their output, these errors assume critical importance.

Indeed, the problems with spreadsheets are also a *software engineering* problem. Spreadsheet utilities are increasingly accessible to external programs through powerful interfaces, such as those defined for Microsoft Excel in COM [9]. This, combined with the growing desire to cobble applications from fragments in different domain-specific languages, means the reliance on spreadsheets will only grow. Therefore, the reliabilities of an overall software system can increasingly be compromised by a buggy spreadsheet.

In this paper, we tackle the problem of statically detecting errors in spreadsheets. We perform an operation similar to type-checking on the formulae of spreadsheets; following the lead of Erwig and Burnett [4], we call this “unit checking”. We present a collection of rules that help identify weaknesses in spreadsheets that are likely to be errors.

In addition to defining rules, we have also implemented a unit checker. Building the checker and executing it on several spreadsheets helped us identify problems with prior approaches. Our unit checker operates on a mainstream spreadsheet utility, namely Mi-

Microsoft Excel. By using COM, our checker interfaces directly with Excel without the need for human intervention (such as asking the user to save the contents of the spreadsheet in some other format). Excel is weaker than spreadsheet languages such as Forms/3 [2], and provides less information to build an effective checker. Nevertheless, because we do not have the power to change practice, we believe it is important to contend with the vicissitudes of a mainstream utility to make our work most widely applicable.

The rest of this paper is organized as follows. Section 2 motivates our work through a series of examples. These examples lay the groundwork for the formal material that follows. In particular, they present some of the subtleties that arise in validating spreadsheets; not treating these weakens prior work in this area. Section 3 erects a formal framework for validating spreadsheets, presenting judgement rules for units. In section 4 we briefly discuss some details of our implementation. Section 5 describes the results we obtained by testing some off-the-shelf spreadsheets. The remaining sections present related work, directions for future work, and concluding remarks.

## 2 Motivating Examples

In this section we introduce the basic concepts and desired behavior of our unit checking system by providing several examples. A very simple table is shown in Figure 1. Intuitively, the user should be able to add the numbers in each row and column of the table because each row or column consists of compatible units. For example, cells B3 and B4 are both in units of TVs, so we can add them together to get another number in units of TVs. We can also add cell B3 to C3, because they both have units of the year 2001. The result, D3, will be in units of 2001, and moreover, we can abstract over the specific type of electronic device in each cell and determine that the result is also in units of Electronics. On the other hand, if the user tries to add B3 and C4 (perhaps because of a formula error), this will cause a unit-checking error, because these cells do not have either a year or a type of device in common.

	A	B	C	D
1		Electronics		
2	Year	TVs	VCRs	Total
3	2001	751	522	1273
4	2002	803	510	1313
5	Total	1554	1032	2586

Figure 1. Electronics Production by Year

2		TVs		VCRs				
3	Year	Total	Defective	Okay	Total	Defective	Okay	Tot. Def.
4	2001	751	6	745	522	3	519	9
5	2002	803	7	796	510	2	508	9
6	Total	1554	13	1541	1032	5	1027	18

Figure 2. Electronics Production Minus Defective Products

Figure 2 shows a slightly more complicated table. Here, TVs and VCRs are subdivided into three categories each. As before, we can perform an operation on cells B4 and C4 because they both have units of 2001 and abstract to units of TVs. We also want to be able to handle column H, which contains the sum of defective TVs and VCRs. We see that cells C4 and F4 have the unit 2001 in common. They are also both Electronics and Defective, but they do not have the intermediate category of either TVs or VCRs in common. Ideally, we would like our unit system to capture this information by assigning the result units of 2001 and Defective Electronics.

	A	B	C	D
1		Gross Sales		
2	Year	TVs	VCRs	Total
3	2001	149723	95176	244899
4	2002	153072	93129	246201
5	Total	302795	188305	491100
6		Costs		
7	Year	TVs	VCRs	Total
8	2001	107925	77293	185218
9	2002	109392	72652	182044
10	Total	217317	149945	367262
11		Profits		
12	Year	TVs	VCRs	Total
13	2001	41798	17883	59681
14	2002	43680	20477	64157
15	Total	85478	38360	123838

Figure 3. Electronics Sales and Profits

Finally, consider Figure 3. If we follow the pattern laid out above, D3 will have units of the year 2001 and Gross Sales, because we will “abstract” over TVs and VCRs and find that B3 and C3 have Gross Sales in common. This seems slightly odd, since Gross Sales is not a supercategory of TVs and VCRs the same way Electronics is. We also want to subtract B9 from B3 to obtain B15, but B3 and B9 have only the subcategory TVs in common, and no common supercategory at all.

In the remainder of this paper, we describe a unit system that will allow us to perform all these opera-

tions, as well as preventing errors such as adding B4 to C5 in Figure 2 (see Section 4 for the error report displayed in this case) or subtracting C9 from B3 in Figure 3. This unit system is insensitive to the specific arrangement of data, so that if the user chooses to present the data in Figure 3 differently (see Figure 4), the results of unit checking will be exactly the same.

	A	B	C	D

### 3 The Unit System

We now proceed to discussing our type system, given the previous examples of the desired behaviour of our checker. First we describe our model of spreadsheets, defining key concepts such as headers and relationships. We then introduce units, the basic elements of our system upon which error checking occurs. In the heart of this section, we present rules to govern how units may be built from spreadsheet cells, starting with simple units, before progressing to more complex units created from cells containing mathematical operations.

#### 3.1 Headers and Relationships

We consider spreadsheets to be comprised of cell *locations*, *values*, and *expressions*. Cell locations are given by their addresses, which we take from the Excel grid system. Values in spreadsheets are typically numbers or strings, but may include other data types as well. Some cells contain expressions, and may include operations on the values of other cells referenced by their locations. The evaluation of an expression yields a value.

A *header* is a concept that defines the common unit for a group of cells. Some cells contain values that

provide names for headers, and we call these *header cells*. For example, in Figure 1, B1 is a header cell containing the value *Electronics*, which is the header for TVs, VCRs, and Total (in cell D2). We assume that each header cell defines a different header, unless it contains a reference to another header cell. For example, in Figure 1, the value *Total* appears in cell A7 as a total over Years and in cell D2 as a total over Electronics. In this case, although these header cells contain the same value, they define two different headers. On the other hand, in Figure 2, the value *Defective* in cell F3 comes from a reference to C3, so these two cells define the same header.

Note that a single cell may have more than one header. For example, cell B3 in Figure 1 has two headers, TVs and 2001. In addition, there may be cells whose headers are not defined explicitly by header cells. Figure 3 illustrates this situation. Here the TVs and VCRs cells are both electronic goods, so they implicitly share a header we will call *Electronics*, though there is no cell to indicate this. The problem of inferring implicit header information will be discussed further in section 4. We assume in our unit-checking system that all headers are known.

There are two kinds of *relationships* that can exist between headers in our unit system. These relationships, common to many type systems, are the *is-a* and *has-a* relationships. We use the *is-a* relationship for both instances and subcategories, so that in Figure 1, we say that 2001 *is-a* (instance of) Year and that TVs *is-a* (subcategory of) Electronics. The *has-a* relationship generally describes properties of items or sets. For example, we can say that in Figure 3, the set of TVs *has-a* (property called) Gross Sales.

#### 3.2 Units

Units form the basic elements upon which we perform error checking. Every cell has a unit determined by the cell’s headers and the relationships those headers participate in. The simplest unit is the Top unit. Any cell that has no headers has unit Top. Examples from Figure 3 are cells A2 (Year) and B1 (Gross Sales). Header cells that participate in *is-a* relationships have hierarchical *is-a* units, which we denote with square brackets. The unit of cell C3 in Figure 2 (Defective) is therefore written Top[Electronics[TVs]]. Since all *is-a* hierarchies are ultimately derived from Top, we will generally leave Top out when describing units from this point onward.

Non-header cells have somewhat more complex units. The unit of every non-header cell contains exactly one *has-a* relationship, which we denote with

braces. This is because a *has-a* relationship uniquely identifies the kind of data present in a value cell. If there were more than one *has-a* relationships, we would need to represent multiple data values in that cell, which is impossible. For the same reason we cannot have units made entirely of *is-a* relationships, although the *has-a* relationship might be implicit, as described below. In addition, non-header cells may have an arbitrary number of headers, each of which defines its own *is-a* hierarchy. We create units with multiple *is-a* hierarchies using the  $\&$  operator. For example, cell B3 in Figure 3 has two headers, 2001 and TVs. The TVs header is related to the Gross Sales header by the *has-a* relationship, so the unit for B3 is:

Electronics[TVs]{Gross Sales} & Year[2001]

Note that, like other headers, the header defining the *has-a* portion of a cell's unit may not be explicitly given in the spreadsheet. The tables in Figures 1 and 2, for instance, do not list this header explicitly. However, we can see by looking at the tables that the property described by the data is a **Number** or **Quantity** of electronic devices. That is, each set of devices listed in the table *has-a* **Quantity**. The unit for cell B3 in Figure 1 is therefore similar to the previous example:

Electronics[TVs]{Quantity} & Year[2001]

Now that we have covered headers and units, we focus our attention on the description of well-formed units. We observe the following conventions for notation:

- $I(d)$  is the *is-a* header for header  $d$  (possibly  $\emptyset$ )
- $U(d)$  is the unit for header  $d$
- $\mathcal{I}(a)$  is the set of *is-a* headers for the cell at location  $a$
- $\mathcal{U}(a)$  is the unit for the cell at location  $a$
- $d \rightarrow h$  holds header  $d$  *has-a* header  $h$
- $v(a)$  is the value of the cell at location  $a$
- $\vec{u}(= u_1[u_2[\dots[u_n]\dots]])$  is the short-hand representation for a hierarchy of *is-a* relationships
- if  $\vec{u} = u_1[\dots[u_n]\dots]$  then  $\vec{u}[u'] = u_1[\dots[u_n[u']]\dots]$

The four categories of elements for which we compute units are:

1. Headers. The unit for a header is determined by its *is-a* relationships. Every header itself has either

zero or one *is-a* headers. In the former case, the header's unit is  $\text{Top}^1$ :

$$\frac{\vdash I(d) = \emptyset}{\vdash U(d) = \text{Top}}$$

Otherwise, its unit is a concatenation of its header's unit and its header's name:

$$\frac{\vdash I(d) = d' \quad \vdash d' \neq \emptyset \quad \vdash U(d') = \vec{u}}{\vdash U(d) = \vec{u}[d']}$$

We define the unit of a header cell to be the unit of the header it names.

2. Non-header cells containing values (i.e. user data), such as cell B3 in Figure 1. These cells also obtain units from their headers. Every cell containing user data must have at least one *is-a* header. Moreover, there must be exactly one *is-a* header with a *has-a* relationship. In the case where a cell has only one *is-a* header, the cell's unit is formed by concatenating its header's unit and header's name as above to obtain the *is-a* part of the unit, and adding the *has-a* header at the end:

$$\frac{\vdash \mathcal{I}(a) = \{d\} \quad \vdash U(d) = \vec{u} \quad \vdash d \rightarrow h}{\vdash \mathcal{U}(a) = \vec{u}[d]\{h}}$$

When a data cell has more than one *is-a* header, each *is-a* header defines its own *is-a* hierarchy, and the results are combined using the  $\&$  operator:

$$\frac{\begin{array}{l} \vdash \mathcal{I}(a) = \{d, d_1, \dots, d_n\} \\ \forall i \in 1..n : U(d_i) = \vec{u}_i \\ U(d) = \vec{u}_d \quad d \rightarrow h \end{array}}{\vdash \mathcal{U}(a) = \vec{u}_d[d]\{h\} \& \vec{u}_1[d_1] \& \dots \& \vec{u}_n[d_n]}$$

3. Cells containing references only, such as cell E3 in Figure 2. The unit of a cell containing a reference is the unit of the cell it refers to.

$$\frac{\vdash v(a) = a'}{\vdash \mathcal{U}(a) = \mathcal{U}(a')}$$

<sup>1</sup>The bottom part of a judgement rule is what the unit checker is able to infer based on the preconditions present in the top part of the judgement. See Pierce's book [13] for a detailed explanation of type systems.

4. Cells containing formulas, such as cell B5 in Figure 1. These cells contain expressions involving mathematical operators, and the resulting unit for this kind of cell depends upon the actual operator in use. We discuss the rules needed for our unit system to support the four basic mathematical operators (+, -, \*, /) in the following subsection.

### 3.3 Units and Mathematical Operators

In this section we motivate and describe the behavior of our system with regard to mathematical operations. The formal judgements for these operations are listed in full in the Appendix. The section introduces these judgements in a less formal way, making use of the Excel examples.

We begin with the simplest example, Figure 1. We want to be able to add the quantity of TVs and VCRs. Intuitively, we can think of trying to union the set of TVs and VCRs to get a combined set. The resulting set will still represent quantities (the *has-a* relation) but we want the union to be described by only the common part of TVs and VCRs. In our unit notation this means that

$$\text{Electronics[TVs]\{Quantity\}} + \text{Electronics[VCRs]\{Quantity\}}$$

when unit-checked should yield:

$$\text{Electronics\{Quantity\}}$$

Essentially, we want to keep the *has-a* part unchanged and perform a union operation,  $\oplus$ , on the *is-a* part of the unit. In general, we have:

$$\frac{\vdash \vec{u}_1\{h\} \quad \vdash \vec{u}_2\{h\}}{\vdash \vec{u}_1\{h\} + \vec{u}_2\{h\} \rightarrow \vec{u}_1 \oplus \vec{u}_2\{h\}}$$

Thus, when we add two units, if they have the same *has-a* part, the result is the union of their *is-a* part. There is an underlying principle here that is the core of the addition rule: in order to add two units together, they must have something in common (in this case the *has-a* part). Now consider the case where the two units have a common *is-a* part. Here is a variant of the example in Figure 3:

$$\text{Electronics[TVs]\{Costs\}} + \text{Electronics[TVs]\{Profits\}}$$

Clearly, we cannot perform a union operation on *Costs* and *Profits*, because they are both properties of the same set, namely *TVs*. By adding *Costs* and *Profits*, we obtain a new property of the same set of *TVs*. In general, this new property will be some irreducible combination of the two old properties. Using the  $\circ$  combinator to indicate the new compound property, the result

of the previous equation therefore becomes:

$$\text{Electronics[TVs]\{Cost \circ Profit\}}$$

Or, in general:

$$\frac{\vdash \vec{u}\{h_1\} \quad \vdash \vec{u}\{h_2\}}{\vdash \vec{u}\{h_1\} + \vec{u}\{h_2\} \rightarrow \vec{u}\{h_1 \circ h_2\}}$$

There is only one situation that we haven't covered yet, the one where both the *is-a* part and the *has-a* part of the unit differ:

$$\text{Electronics[TVs]\{Cost\}} + \text{Electronics[VCRs]\{Profit\}}$$

This equation clearly violates our principle stating that units must have either the *is-a* part or the *has-a* part in common in order for the addition to pass the unit checker. Intuitively, also, we see that this is the kind of operation we want to prevent, as it could only result from a mistake made by the user.

We turn our attention now to the  $\oplus$  rule, as it is an important part of the addition operation. We quickly glanced over it in the first example of the section, when we obtained *Electronics* from *Electronics[TVs]*  $\oplus$  *Electronics[VCRs]*. The  $\oplus$  rule applied to the *is-a* parts of the units, and combined them by retaining in the result only the common parts of the two units. Judging from our first example, it might seem that the result of the union operation will always be a more general unit than either of the two arguments. But suppose we want to perform a union operation on these two units:

$$\text{Electronics[TVs[Wide-Screen[Defective]]]} \oplus \text{Electronics[VCR[Defective]]}$$

In this case we could also say that the result should be *Electronics*, but we would lose information common to the two original units: the fact that they are both defective. Instead, our desired result is:

$$\text{Electronics[Defective]}$$

The  $\oplus$  operation therefore combines the *is-a* parts of two units creating a new unit from all the common features of the two units, not just the most general ones.

To summarize, the addition rule applies only to units that either have identical *has-a* parts, in which case the result is a  $\oplus$  operation on their *is-a* parts; or identical *is-a* parts, in which case the result is a  $\circ$  operation on their *has-a* parts.

Now that we have seen how addition works, we will describe subtraction. As with addition, we want to allow subtraction only between cells that have either identical *has-a* or *is-a* parts. We begin with the first case. In Figure 2, the *Okay* column for *TVs* requires us to subtract the following two units:

$$\text{Electronics[TVs[Total]]\{Quantity\} - Electronics[TVs[Defective]]\{Quantity\}}$$

We want our unit checker to identify the result as representing a quantity of TVs:

$$\text{Electronics[TVs]\{Quantity\}}$$

We cannot be any more specific about the unit of the result, since there is no way to know in general whether the set resulting from a subtraction operation contains any items of the subtracted type. In other words, we may not have subtracted all the defective TVs from the original set. We only know that, since both original sets were types of TVs, we must still have a set containing only TVs (of some type). This result is satisfying, since it exactly mirrors the behavior of addition, where we apply  $\oplus$  operator to the *is-a* parts.

Now consider subtracting two units with a common *is-a* part, as in Figure 3, where the data in the Profit column is given by:

$$\text{Electronics[TVs]\{Gross Sales\} - Electronics[TVs]\{Costs\}}$$

As with addition, the result is the combination of the *is-a* part, Electronics[TVs], and a new property derived from Gross Sales and Costs:

$$\text{Electronics[TVs]\{Gross Sales } \circ \text{ Costs\}}$$

Having seen how addition and subtraction work, we can conclude that any binary operator must correctly handle two cases: identical *is-a* parts and identical *has-a* parts. In the case of identical *is-a* parts, the result of the operation is always a compound of the two different *has-a* parts. For example, suppose we have a computation for the area of a rectangle:

$$\text{Shape[Rectangle]\{Length\} } \times \text{Shape[Rectangle]\{Width\}}$$

It is obvious we want to remember that the result is given by the combination of Length and Width:

$$\text{Shape[Rectangle]\{Length } \circ \text{ Width\}}$$

We conclude, therefore, that when dealing with identical *is-a* parts, any binary operator returns a  $\circ$  combination of the *has-a* parts along with the *is-a* part as the result.

Is the case of identical *has-a* parts also uniform across all binary operators? We have seen that both addition and subtraction require the use of the  $\oplus$  operator on the different *is-a* parts. But suppose we have the following equation:

$$\text{Shape[Rectangle]\{Length\} } \times \text{Shape[Square]\{Length\}}$$

Clearly it does not make sense to have Shape{Length} as the result. In fact, there is no satisfactory combination of the two *is-a* parts that will accurately describe the result. However, we do not want to flag this as an error, since there might be a legitimate reason for the user to perform this operation. Therefore, when dealing with any binary operator other than + or -, the result of combining two units with different *is-a* parts and the same *has-a* part is always Top{h} (where h is the common *has-a* part).

To obtain meaningful results from constructs such as:

$$\text{Shape[Square]\{Length\} } \times \text{Shape[Square]\{Length\}}$$

the identical *is-a* combination,  $\circ$ , takes precedence over the identical *has-a* combination,  $\oplus$  or Top.

Finally, we will describe the *and*(&) operation. As briefly noted in section 2, the unit of cell B3 from Figure 1 is:

$$\text{Electronics[TVs]\{Quantity\} } \& \text{Year[2001]}$$

The unit of a value cell that has more than one header is given by the & constructor on the units inferred from each individual header. There are restrictions on the types of the units on which we can perform &.

Each header conveys a distinct property for the data in the cell, which means that a well-formed & unit consists of different, header inferred, units containing only *is-a* parts, with only one of them potentially having a *has-a* part. Since there is only one *has-a* part at most, the difference applies to the *is-a* parts of the units. Two *is-a* parts are different if and only if their top labels are different because only then do the two *is-a* parts represent disjoint data properties. The & operation is idempotent to handle the special case when two *is-a* parts are identical. For example, Electronics and Year are clearly different so it is correct to join them through &. On the other hand,

$$\text{Electronics[TVs] } \& \text{Electronics[VCRs]\{Gross Sales\}}$$

does not represent a valid & unit operation because both headers represent Electronics and that contradicts our requirement that the headers differ.

The & operation is distributive with respect to any other binary operation between units. For example, in Figure 1, cell B5 has unit:

$$\text{Electronics[TVs]\{Quantity\} } \& \text{Year[2001] } + \text{Electronics[TVs]\{Quantity\} } \& \text{Year[2002]}$$

which reduces to:

$$\text{Electronics[TVs]\{Quantity\} } \& (\text{Year[2001] } + \text{Year[2002]})$$

We want the unit checker to perform the addition on the two *is-a* units as if there were an empty *has-a* part, yielding the following result:

Electronics[TVs]{Quantity} & Year

We thus handle the reduction of Year[2001] + Year[2002] using the special case of the identical *has-a* rule for binary operations, the one with empty *has-a* parts.

#### 4 Implementation

Our unit checker is implemented in the DrScheme programming environment [6]. It has three components: a GUI, an I/O layer that mediates the communication with Excel, and the unit checker itself.

The GUI, Figure 5, is implemented using MrEd, the windows tool for DrScheme. The user can start an instance of a desired spreadsheet with the Load File button. Analyze will check the loaded spreadsheet once it is annotated with the right units. In earlier sections we relied on a header inference algorithm to correctly annotate cells with units based on header labels. Header inference is a difficult artificial intelligence and natural language processing problem. Our current implementation does not have such an algorithm. Instead, the value cells are annotated with the right units through the GUI. A range of cells is selected either with the mouse in Excel, or textually entered in the Cell(s) Range(s) field in the GUI and their corresponding unit in the Cell(s) Units field. The Assign Units button updates, in Excel, the comment field of every cell from the range with the assigned unit. In the future we plan to provide a more automated process for unit inference. To that end, we may do semantic analysis on headers to determine relationships with the aid of WordNet [5].

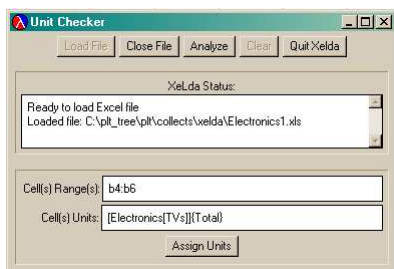

Figure 5. Unit Checker GUI

We use the MysterX [17] Component Object Model (COM) extension to DrScheme to communicate with Excel. Although Excel has a complex COM model

(over 400 COM interfaces), we only need a few of those for our tool. Examples of the interfaces we need are: `_Application`, `_Worksheet`, `_Range`. Each of these has methods and properties through which the application can mimic any user interaction with Excel. Our I/O layer implements the functionality needed by the tool (such as coloring cells, adding comments to cells, etc.) by using MysterX methods.

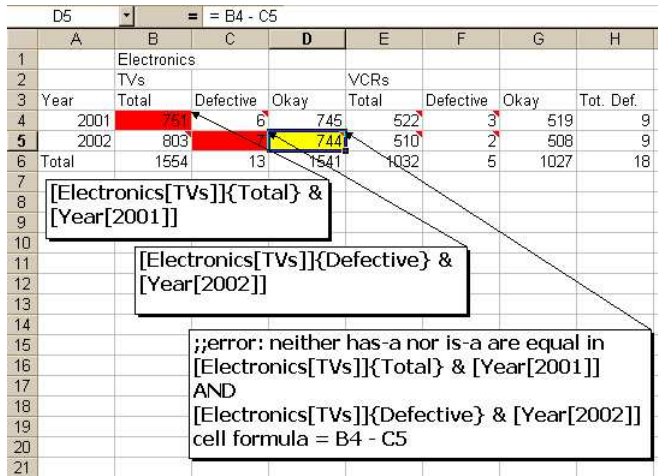

Figure 6. Unit Error

Unit errors are reported back to the user by coloring the offending cells. Figure 6 is similar to Figure 2 except we have deliberately introduced an error in cell D5. For each error cell, the user can display the input cells to the formula in that cell by right clicking the mouse. In Figure 6 the input cells for D5 are B4 and C5. There are two kinds of errors reported back. The unit errors are those where the unit checker identified a problem in the formula for the cell, as is the case with cell D5. There are also propagation errors. Those are cells that in their formula use a reference to another cell that was flagged by the unit checker as containing an error.

Our judgements do not dictate an order on checking a spreadsheet. In our current implementation we assign units to value cells through the GUI. All the other cells will contain formulas and therefore their units will be inferred. From Excel we extract a list of all the formulas and then unit check each one in a recursive manner by computing units for subformulas first and then combining them by using our inference rules. Since Excel provides cycle detection, we do not concern ourselves with circularity and furthermore this approach is guaranteed to terminate.

Excel has over 300 pre-defined functions. These functions can be grouped together based on their do-

mains. For example there are financial functions, matrix operators, trigonometric functions, etc. We chose representatives of each of these groups and implemented inference rules for them based on our base inference rules. In order to be fully functional, our checker would need to implement judgement rules for all the functions and this is something we plan to do in the future.

## 5 Applying the Unit Checker

We have tested our unit checker on some off-the-shelf spreadsheets. The book by Filby [14] contains a collection of scientific spreadsheets from a variety of engineering fields. None of the spreadsheets had any unit annotations. We used our tool to annotate the value cells in those spreadsheets with the correct units.

The table in Figure 7 describes the spreadsheets we used to test our unit checker. The size given is the number of non-empty cells. The **COM** column represents the time the application spent communicating with Excel through COM using the Automation method. The **Checker** column represents the actual unit checking time. Both column times are in minutes and seconds, as provided by PLT Scheme’s `time` macro. From the table it is clear that the application spends most of its time interacting with Excel. COM Automation is a well-known performance bottleneck. In the future we plan to use the COM Direct Interfaces or .NET when Excel will be accessible through it to speedup the application’s interaction with Excel.

There is one entry in the **Checker** column marked with  $\checkmark$ . Surprisingly to us, our unit checker found an error in the marked spreadsheet. The author of that spreadsheet uses an Excel formula, `FREQUENCY`, that takes two ranges of cells as arguments. The second range he entered was incorrect in that it used one extra cell that did not contain any data and our unit checker correctly identified that misuse.

Although lacking a header inference mechanism, there was very little time and effort involved when we used our tool on the existing spreadsheets. Our experience suggests that the unit checker offers great promise to be a useful tool for real-world users of spreadsheets.

## 6 Related work

The most closely related work is the unit checker of Erwig and Burnett [4]. Their system is based on the same principles as ours. There is, however, a significant difference between their formulation and ours. Their system fails to distinguish between the *is-a* and *has-a* relationship. Additionally our system is capable of

handling subtraction in cell expressions. These changes lead to a more thorough type system. We present the following examples to highlight valid spreadsheets that would be allowed to pass unhindered by our system, yet fail to pass through the system in [4].

In Figure 4, we rearrange the tables in Figure 3, and assume that the header inference is able to infer that TVs and VCRs are both types of electronic goods. Consider the operation in cell B15. First we discuss how Erwig and Burnett’s checker would operate in this situation. In their system, cells B3 and B9 have units `All Electronics[TVs[Gross]]` and `All Electronics[VCRs[Gross]]` respectively. The subsequent addition operation in cell B15 fails, because the hierarchies of the two units differ in their second components (TVs vs. VCRs), despite the common third component of `Gross`. The header inference could conceivably reverse the hierarchy of the units. Cells B3 and B9 could be assigned units of `Gross[TVs]` and `Gross[VCRs]`, enabling cell B15 to pass the unit checking. However the computation of profits, in cell D3 for example, would now fail (`Cost[TVs]` cannot be subtracted from `Gross[TVs]`). Our system handles this case in exactly the same manner as described above. Cell B15 turns out to be an addition of:

$$\text{All Electronics[TVs]\{Gross\}} + \text{All Electronics[VCRs]\{Gross\}} = \text{All Electronics}\{Gross\}$$

Cell D3 is:

$$\text{All Electronics[TVs]\{Gross\}} - \text{All Electronics[TVs]\{Cost\}} = \text{All Electronics[TVs]\{Gross \circ Cost\}}$$

This demonstrates that despite any rearrangement of the tables, providing the header inference is able to determine the relationships in the manner above, our rules may be consistently applied. Erwig and Burnett’s system is unable to handle an intuitive way of tabulating data, and no rearrangement of headers is able to account for the differences in the *is-a* and *has-a* relationships. These failures were highlighted while we implemented their unit checker, which Erwig and Burnett lacked.

There have been other works tackling the specific problem of detecting errors in spreadsheets. Rothermel et al. [16] apply an adaptation of testing mechanisms for imperative programs to spreadsheets. This aims at detecting the most common of spreadsheet errors, cell reference errors in cell expressions [12], through the use of data flow adequacy criteria. The authors define the data flow test adequacy criteria employed, in terms of definition-use (du) associations that are involved in visible cell outputs. Relying on user interaction to validate the values in cells, the system marks

du-associations as having been exercised, and visually reflects the percentage of all du-associations exercised per cell with shades of colors. Rothermel et al. apply this kind of testing to the Forms/3 spreadsheet language [2], whereas our system pertains to Excel spreadsheets. Specifically, Excel spreadsheets are able to detect the use of blank cells in cell expressions. Thus the types of errors we are able to detect are of a different nature, and this belief is reinforced if we consider the following example. In Figure 1, suppose the cell B5 contained the cell expression B3 + C4. Our type system would flag an error due to the addition of the types:

Electronics[TVs]{Quantity} & Year[2001] +  
Electronics[VCRs]{Quantity} & Year[2002]

However the system in [16] would not be able to detect this problem in Figure 1.

Kennedy [8] describes an extension of strongly-typed programming languages to include polymorphic dimension types for values within the language, stemming from a similarity between well-typedness of programs and dimensional consistency of mathematical expressions. The author introduces the concepts of base dimensions as dimensions that cannot be defined in terms of others, such as length, mass, time, etc. The counter to these are derived dimensions, for example acceleration which can be thought of as length divided by time squared. Units are also discussed. These units are not to be confused with the units we check, but are units of measurement, such as meters, or kilograms. Base units are used to measure the base dimensions, and alternative units of measurement are considered a scaling of base units.

## 7 Conclusion and Future Work

In this paper we have presented a methodology for detecting errors of a semantic nature in spreadsheets. We have introduced the concept of the *is-a* and the *has-a* relationships, whose essence is found in a large number of type systems, into the domain of spreadsheets. In the process, we have enhanced the completeness of our type system in comparison to existing work, by broadening the range of units that may pass unit checking. This is important because users will disable a checker if it reports errors on valid inputs.

Our implementation provides a simple interface to unit check an Excel spreadsheet. While we have not delved deeply into the problem of header inference for a wide range of spreadsheets, our unit checker is able to detect errors in many cases without any additional information than that present in the spreadsheet.

## A Appendix: Unit inference rules

Let:

- $\nabla \equiv$  any binary operator
- $\nabla^* \equiv$  any binary operator except for  $+/-$
- $I(d)$  are the *is-a* headers for header  $d$  (possibly  $\emptyset$ )
- $U(d)$  is the unit for header  $d$
- $\mathcal{I}(a)$  are the *is-a* headers for the cell at location  $a$
- $\mathcal{U}(a)$  is the unit for the cell at location  $a$
- $d \rightarrow h$  shows header  $d$  *has-a* header  $h$

- $v(a)$  is the value of the cell at location  $a$ .
- $\vec{u}$  ( $= u_1[u_2[\dots[u_n]\dots]]$ ) is the short-hand representation for a hierarchy of *is-a* relationships.
- if  $\vec{u} = u_1[\dots[u_n]\dots]$  then  $\vec{u}[u'] = u_1[\dots[u_n[u']]\dots]$

### Unit construction rules:

Headers:

$$\frac{\vdash I(d) = \emptyset}{\vdash U(d) = \text{Top}}$$

$$\frac{\vdash d' \in I(d), U(d') = \vec{u}}{\vdash U(d) = \vec{u}[d']}$$

Values:

$$\frac{\vdash d \in \mathcal{I}(a) \quad \vdash U(d) = \vec{u} \quad d \rightarrow h}{\vdash \mathcal{U}(a) = \vec{u}[d]\{h}}$$

$$\frac{\vdash \{d, d_1, \dots, d_n\} = \mathcal{I}(a), \forall i \in 1..n : U(d_i) = \vec{u}_i}{\vdash \mathcal{U}(a) = \vec{u}_d[d]\{h\} \ \& \ \vec{u}_1[d_1] \ \& \ \dots \ \& \ \vec{u}_n[d_n]}$$

References:

$$\frac{\vdash v(a) = a'}{\vdash \mathcal{U}(a) = \mathcal{U}(a')}$$

$\oplus$ -rule :

$$\vec{u}_1 = c_1[\dots[c_i[x_1 \dots [x_k[c_{i+1} \dots [c_j] \dots]] \dots]] \dots]$$

$$\vec{u}_2 = c_1[\dots[c_i[y_1 \dots [y_l[c_{i+1} \dots [c_j] \dots]] \dots]] \dots]$$

$$\frac{\vdash \vec{u}_1 \quad \vdash \vec{u}_2 \quad i > 0; j \geq i; k, l \geq 0}{\vdash \vec{u}_1 \oplus \vec{u}_2 \rightarrow c_1[\dots[c_i \dots [c_j] \dots]] \dots]}$$

$\&$ -rule:

$$\vec{u} = u_1[\dots[u_i] \dots]$$

$$\vec{v} = v_1[\dots[v_j] \dots]$$

$$\frac{\vdash \vec{u} \quad \vdash \vec{v} \quad u_1 \neq v_1}{\vdash \vec{u} \ \& \ \vec{v}}$$

Simplification rules:

$$\vec{u}_1 \ \& \ (\vec{u}_2 \ \& \ \vec{u}_3) = (\vec{u}_1 \ \& \ \vec{u}_2) \ \& \ \vec{u}_3 = \vec{u}_1 \ \& \ \vec{u}_2 \ \& \ \vec{u}_3$$

$$\vec{u}_1 \ \& \ \vec{u}_2 = \vec{u}_2 \ \& \ \vec{u}_1$$

$$\vec{u} \ \& \ \vec{u} = \vec{u}$$

$$\vec{u}_1 \ \& \ (\vec{u}_2 \ \nabla \ \vec{u}_3) = \vec{u}_1 \ \& \ \vec{u}_2 \ \nabla \ \vec{u}_1 \ \& \ \vec{u}_3$$

Identical *is-a* rule:

$$\frac{\vdash \vec{u}\{h_1\} \quad \vdash \vec{u}\{h_2\}}{\vdash \vec{u}\{h_1\} \ \nabla \ \vec{u}\{h_2\} \rightarrow \vec{u}\{h_1 \circ h_2\}}$$

Identical *has-a* rule, *has-a* can be empty:

$$\frac{\vdash \vec{u}_1\{h\} \quad \vdash \vec{u}_2\{h\}}{\vdash \vec{u}_1\{h\} \ \pm \ \vec{u}_2\{h\} \rightarrow \vec{u}_1 \oplus \vec{u}_2\{h\}}$$

$$\frac{\vdash \vec{u}_1\{h\} \quad \vdash \vec{u}_2\{h\}}{\vdash \vec{u}_1\{h\} \ \nabla^* \ \vec{u}_2\{h\} \rightarrow \text{Top}\{h\}}$$
