Debugging Java Programs with CodeWarrior for CS100 and CS211

Hal Perkins
Spring 1998

CodeWarrior includes an interactive debugger that you can use to examine your program as it executes. This handout gives an overview of the debugger and how to use it effectively.

If you’re just learning to program, some of the information in this handout may not make much sense until later in the course when topics like arrays have been covered. Skim over unfamiliar material now and read it again later when those topics are introduced.

1 Perspective

An interactive debugger is the software equivalent of a logic probe or a CAT scan. It allows you to run your program a few statements at a time, observe the values of variables, and even make temporary changes in the middle of execution. A good interactive debugger is an invaluable tool for finding problems and verifying that a program works.

But a debugger is no substitute for thinking. The best way to eliminate errors (bugs) is not to create them in the first place. Time spent carefully designing a program is more than repaid in time saved during testing and debugging. Before you start writing detailed code be sure you understand the problem and the algorithms you plan to use to solve it. After you've written the code, carefully check it (proofreading, tracing, etc.) before you try running it.

Don’t rush to get something on the computer. You may be tempted to type in the first thing that comes to mind and start tinkering with it, because it sometimes feels like no progress has been made until the machine is involved. But if you hack before you know what you are doing, it will take much longer to get a working program and the code will be much worse.

If you find that you are tinkering with your code, randomly changing things in the hope that the bugs will go away, get away from the computer immediately before you do any more damage.

Take advantage of all error-detecting features provided by CodeWarrior. Turn on any options that you can find to generate warning messages. Use any available software tools to look for potential bugs. Don’t waste your time on problems the computer could have caught for you.

Once you have carefully designed and entered your code, your task is to verify that it works as expected. The debugger can be a great help with this, allowing you to stop execution at “interesting” places and check that variables have their expected values, that expected output has been produced, and that nothing unexpected has happened.

2 Using the Debugger

To use the CodeWarrior debugger, select Enable Debugger from CodeWarrior menu Project. (On a Mac, this changes the Run command in menu Project to Debug.) Then select Debug to have the debugger take control of your program.

The debugger’s program and browser windows usually open automatically when the debugger starts. If they don’t appear, you can select them from menu Window. In the screen snapshot on the last page of this handout, the browser window is in the upper right corner with the program right below it.

The program window contains two panes on top and a larger one on the bottom. It displays information about currently active methods and the source files that contain them. A list of active methods is in the upper-left panel. The bottom panel displays the source file containing the method whose name is selected in the list and the upper-right panel displays its local variables. An arrow appears to the left of the next statement to be executed in each active method. Initially execution is paused at the first statement of method main.

The browser window looks much like the program window, but contains three panes at the top. It can be used to view any file in the program, not just those containing currently active methods. The upper-left pane of this window contains a list of files in the pro-
gram. When a file name is selected, the middle pane contains a list of the methods in that file. Select a method name to view its source code in the bottom pane.

You will need to arrange the debugger’s windows on the screen so they don’t overlap other windows, like the input/output console window, that you want to see while debugging. You can change the size of the debugger’s windows by dragging the lower right corner as usual. To adjust the size of individual panes in the windows, use the mouse to drag the vertical or horizontal bars between them.

Once the debugger has launched, you can run your program by selecting Run from debugger menu CONTROL. You may need to select Run twice if the first attempt only brings the program window forward without actually starting it.

2.1 Breakpoints

Before you run your program, you will probably want to set breakpoints: places in the code where you want execution to pause so you can examine the situation before continuing. Breakpoints can be set in both the program and browser windows. In the source panes of these windows, there are dashes to the left of most statements, indicating places where breakpoints can be set. (This is a good reason to put individual statements on separate lines. Breakpoints cannot be placed in the middle of a line of code — only at the beginning.)

To set a breakpoint, click one of the dashes. It will turn into a small red dot. When the execution reaches an active breakpoint, the program pauses and control returns to the debugger.

The breakpoints window contains a list of all the breakpoints in the program. If it is not on the screen, you can select it from menu WINDOW.

You can temporarily disable a breakpoint without removing it entirely by clicking the red dot next to it in the breakpoints window. The dot changes to a dash. The breakpoint still exists in the program, but execution won’t pause there. This is useful, for example, if you want to stop at a breakpoint the first time it is reached but not after. To reactivate a breakpoint, click the dash in the left column of the breakpoint window to cause the red dot to reappear.

You can also add a condition to a breakpoint. When a breakpoint has a condition attached to it, execution will pause only when the breakpoint is active and the condition is true. Conditions — logical expressions (e.g. sum >= 17) — are entered in the breakpoints window to the right of the affected breakpoint.

You can view the location of a breakpoint in the source program by double clicking it in the breakpoints window. The browser window will jump to that location.

To permanently remove a breakpoint from the program, click the red dot next to the statement in the program window or symbol window (not the breakpoints window). The dot will change back to a dash to indicate that the breakpoint is gone.

Note: The CodeWarrior Pro 2 debugger for Windows does not always pause properly at the beginning of method main when it begins executing a program. If the program runs to completion when the debugger starts, use the browser window to select the file containing the class where execution is to begin, (upper-left panel), then select method main (upper-middle panel) and click to the left of the first statement in the program to set a breakpoint. Then select KILL and then RUN from menu CONTROL to debug the program.

2.2 Stopping a Runaway Program

Macintosh. If you need to stop a program you are debugging (perhaps because it is stuck in an infinite loop) type control-command-/. This should return control to the debugger. The program window will show the location in the program where execution is paused, and you can use the debugger to appraise the situation.

If control-command-/ doesn’t work, you can usually force the program to quit by pressing Option-Command-Esc. This will terminate the program. If you want to continue debugging, you will have to start from the beginning.

Occasionally a problem will cause the machine to lock up or freeze. If neither of the above steps salvage the situation, you will have to restart the machine. Don’t do this unless you have to — all unsaved work in open applications will be lost.

Windows. Usually, a runaway Windows program can be stopped by selecting a debugger window, then selecting STOP or KILL from menu CONTROL.

2.3 Incremental Execution

Once a program is stopped, you may want to look around and run it slowly, a few statements at a time. The commands in menu CONTROL do this.

The step commands run the program one statement at a time. Step Over and Step Into both execute the next statement in the program. If that
statement calls a method, **Step Over** executes the entire method call in a single step. **Step Into** moves into the body of the method so you can trace its execution. You will probably want to use **Step Into** to examine your own methods and **Step Over** when calling ones that we supply or that are part of CodeWarrior.

**Step Out** completes execution of the current method and stops at the place where the method was called.

**Run** resumes execution until another breakpoint is reached or until the program terminates.

**Stop** stops the program and returns control to the debugger. Execution can be resumed after executing any desired debugger commands.

**Kill** terminates execution of the program. This is useful if you want to start the program over from the beginning without waiting for it to finish.

**Note:** The debugger’s toolbar is an easy way to access these six commands. The toolbar has buttons for **Run**, **Stop**, **Kill**, **Step Over**, **Step Into**, and **Step Out**, in that order. If the toolbar is not visible, select it from menu **Windows**.

### 2.4 Examining a Program

When the program is stopped, you can examine the values of variables, check whether certain conditions are true or false, evaluate expressions, etc.

#### 2.4.1 The Call Stack

The *call stack* in the upper-left corner of the program window displays a list of currently active methods. The name of the currently executing method appears at the bottom of this list, the name of the method that called it is just above, and so forth. For example, if method **main** called **sort_list**, which called **move_smallest_to_front**, which called **move_element**, the call stack would be:

```
main
sort_list
move_smallest_to_front
move_element
```

Additional methods may be listed above **main**. These methods are either part of CodeWarrior or part of the operating system. Normally you will be interested only in the ones from **main** down.

You can view the source code and local variables of any method in the call stack by selecting its name.

#### 2.4.2 Local Variables

The upper right corner of the program window shows the local and global variables of the method currently selected in the call stack. The current value of each variable appears to the right of its name.

The values of simple variables, with types like **int**, **double**, and **char**, are displayed to the right of the variable name. For arrays and structures, the memory location of the variable is shown and there is a disclosure triangle (▶) to the left of the variable name. Click this button to see the components of the variable (array elements or structure fields). More complex data structures may contain fields that can be further expanded by clicking a disclosure triangle.

**Note:** Uninitialized variables may appear to have nonsense values. For example, if an integer variable has not been initialized, something bizarre like -14853 might be displayed as its value.

To view the value of a variable in a separate window, double click its name or select **Open Variable Window** from menu **Data**.

Other commands in menu **Data** control how information about variables is displayed.

**Show Types** displays the type of each variable along with its value.

**View As...** allows you to set the type according to which a variable is displayed. This is primarily useful for machine level debugging.

**Open Array Window** displays an array in a separate window. **Option**-double-clicking a variable name is a shortcut for this command.

To change the value of any variable while you are debugging, double-click its current value and enter a new one.

**Warning:** This changes the value of the variable only for the current execution of the program. To make a permanent change, you *must* change the original program.

#### 2.4.3 Expressions

You can evaluate expressions in the *expressions* window. Expressions may include program variables or Java operators, but not method calls.

There are two ways to enter expressions in this window. **Copy to Expression**, in menu **Data**, copies any selected expression from the program window to the expressions window. To enter a new expression select **New Expression** from menu **Data**. Type the expression and press **Return**.
To modify an expression, double-click it and make the desired changes. Hit Return to display its value.

2.5 When You’re Done

If you plan to run your program with the debugger again, quit your program (Java console window) but leave the debugger application running. Use CodeWarrior to make any needed changes. When you select Debug again (command-r) the debugger will resume control of the program.

To run the program without the debugger, select Disable Debugger from menu Project. If you want to resume debugging, select Enable Debugger again.

Remember to quit the debugger when you are done. Select Quit from menu File.
