This handout explains what you have to know for the second prelim. There will be a review session with
detailed examples to help you study. To prepare for the prelim, you can (1) practice writing functions and
classes in Python, (2) review the assignments and labs, (3) review the lecture slides, (4) read the text, and
(5) memorize terminology listed below.

The prelim will not cover while loops. It covers material up to and including the lecture on November 6th.
The test will focus on recursion, iteration, and classes (e.g. Assignments 4 - 6, as well as all related labs).

1. Exam Information

The exam will be held Thursday, November 12th from 7:30-9:00 pm. For reasons of space, we are
again split across multiple rooms.

- Students with last names A – J meet in Uris Hall G01
- Students with last names K – Z meet in Statler Auditorium (185)

1.1. Review Session. There will be a review session on Sunday, November 9th at 2pm in a room to
be announced later. It will cover material in this handout and explain the basic structure of the exam. It
will also go over several sample problems to help you prepare for the exam.

2. Content of the Exam

In studying for this exam, you should be wary of looking at the past exams too closely. While Fall 2013 and
2014 are good exams to study from, the other exams are not. The material in all of the Spring semesters is
very different for the second prelim.

Once again, there will be five questions, each of roughly equal weight. These questions will be taken from
some combination of the following six topics:

Recursion. You will be asked to write a recursive function. It will be roughly the complexity of the recursive
functions in the lab (e.g. lab 7); we will not have a Turtle question. The recustion question on the final (not
prelim 2) for Fall 2012 is an excellent example of good recursion exam question.

When writing your recursive function, you should pay attention to the important points:

(1) precise specification
(2) base case(s)
(3) recursive case(s)
(4) progress toward termination.
You should also be prepared to draw a (short) call stack for a recursive function. Think of problem problem 5 from Prelim 1. We have not decided to add such a question yet, but in the past, the really short recursive functions are generally all-or-nothing. This type of question would allow us to test your knowledge of recursion even if you did not do so well on the programming part.

**Iteration.** You will be given a problem that you will need to use a for-loop to solve. You should know how to use a for-loop on a sequence if you are given one, or how to use `range()` if you are not given one. You should know how to use an *accumulator* if needed to perform calculations using a for-loop.

As part of this question, we might ask you to write a function that processes a 2-dimensional list. This would likely require two nested for-loops. If you have completed Part I of A6, you have a lot of experience doing this. We may also ask you to loop over dictionaries, as you did in A4.

**Classes.** You should know how to create a class that includes attributes, getters, setters, an initializer, and methods. You should know the names of the three most important built-in methods (e.g. `__init__`, `__str__`, and `__eq__`), but you do not need to know the names of any of the others. We expect you to be able to construct getters and setters for attributes given a class specification.

You should also know how to create a subclass, and should know how inheritance and overriding work in Python. You should expect to be given a base class and be asked to subclass it to provide additional functionality.

**Diagramming Objects.** You will be given a series of assignments and constructor calls. You will be expected to (1) identify the number of objects that are created, (2) draw folder representations of each of each object, and (3) draw folder representations of each class. You should have a lot of experience with this after Assignment 5.

**Exceptions.** You should know how to raise an exception, and how the new-and-improved try-except statements work. We will give you the exception hierarchy (what is a subclass of what) to help you with this problem.

**Short Answer.** The short answer questions will focus on terminology, particularly regarding object-oriented methodology. For this part of the test, we recommend that you review the text as well as the lecture slides. In addition, we have provided a list of important terminology below.

The short answer questions may also include short, poutporri-style questions that were not long enough to merit a separate category of their own. For example, we might ask a few questions about dictionaries (not covered in any other part of the exam) here.

### 3. Terminology and Important Concepts

Below, we summarize the terms you should know for this exam. You should be able to define any term below clearly and precisely. If it is a Python statement, you should know its syntax and how to execute it. You should know all of this *in addition to* the terminology that you had to learn for the first prelim.
Accumulator. An accumulator is a fancy name for a variable in a for-loop that stores information computed in the for-loop and which will be still available when the for-loop is complete.

Example: In the for loop
```python
total = 0
for x in range(5):
    total = total + x
```
the variable `total` is an accumulator. It stores the sum of the values 0..4.

Attribute. Attributes are variables that are stored inside of an object. Instance attributes belong to an object or instance. Instance attributes are created by assignment statement that prefaces the object name before the period. They are typically created in the class initializer.

Class attributes belong to the class. They are created by an assignment statement that prefaces the class name before the period. They are also created by any assignment statement in the class definition that is outside of a method definition.

It is impossible to enforce invariants on attributes as any value can be stored in an attribute at any time. Therefore, we prefer to make attributes hidden (by starting their name with an underscore), and replacing them with getters and setters.

Example: If the variable `color` stores an RGB object, then the assignment `color.red = 255` alters the red instance attribute. The assignment `RGB.x = 1` would create a class attribute `x`.

Bottom-Up Rule. This is the rule by which Python determines which attribute or method definition to use (when the attribute is used in an expression, or the method is called). It first looks in the object folder. If it cannot find it there, it moves to the class folder for this object. It then follows the arrows from child class to parent class until it finds it. If Python reaches the folder for object (the superest class of all) and still cannot find it, it raises an error.

If the attribute or method is in multiple folders, it uses the first one that it finds.

Class. A class is any type that is not built-in to Python (unlike `int`, `float`, `bool`, and `str` which are built-in). A value of this type is called an object.

Class definition. This is a template or blueprint for the objects (or instances) of the class. A class defines the components of each object of the class. All objects of the class have the same components, meaning they have the same attributes and methods. The only difference between objects is the values of their attributes. Using the blueprint analogy, while many houses (objects) can be built from the same blueprint, they may differ in color of rooms, wallpaper, and so on.

In Python, class definitions have the following form:

```python
class <classname>(<superclass>):
    <class specification>
    <getters and setters>
    <initializer definition>
    <method definitions>
```

In most cases, we use the built-in class `object` as the super class.
Constructor. A constructor is a function that creates an object for a class. It puts the object in heap space, and returns the name of the object (e.g., the folder name) so you can store it in a variable. A constructor has the same name as the type of the object you wish to create.

When called, the constructor does the following:

- It creates an empty object folder.
- It puts the folder into heap space.
- It executes the initializer method __init__ defined in the body of the class. In doing so, it
  - Passes the folder name to that parameter self
  - Passes the other arguments in order
  - Executes the commands in the body of __init__
- When done with __init__ it returns the object (folder) name as final value of expression.

There are no return statements in the body of __init__; Python handles this for you automatically.

Example constructor call (within a statement): color = RGB(255,0,255)

Example __init__ definition:

```python
def __init__(self,x,y):
    self.x = x
    self.y = y
```

Default Argument. A default argument is a value that is given to a parameter if the user calling the function or method does not provide that parameter. A default argument is specified by wording the parameter as an assignment in the function header. Once you provide a default argument for a parameter, all parameters following it in the header must also have default arguments.

Example:

```python
def foo(x,y=2,z=3):
    ...
```

In this example, the function calls foo(1), foo(1,0), foo(1,0,0), and foo(1,z=0) are all legal, while foo() is not. The parameter x does not have default arguments, while y and z do.

Dispatch-on-Type. Dispatch-on-type refers to a function (or other Python command) that can take multiple types of input, and whose behavior depends upon the type of these inputs. Operator overloading is a special kind of dispatch-on-type where the meaning of an operator, such as +, *, or /, is determined by the class of the object on the left. Dispatch-on-type is also used by try-except statements to determine whether to recover from an error.

Duck Typing. Duck typing is the act of determining if an object is of the correct “type” by simply checking if it has attributes or methods of the right names. This much weaker than using the type() function, because two completely different classes (and hence different types) could share the same attributes and methods. The name was chosen because “If it looks like a duck and quacks like a duck, then it must be a duck.”
Encapsulation. Encapsulation is the process of hiding parts of your data and implementation from users that do not need access to that parts of your code. This process makes it easier for you to make changes in your own code without adversely affecting others that depend upon your code. See the definitions of interface and implementation.

Getter. A getter is a special method that returns the value of an instance attribute (of the same name) when called. It allows the user to access the attribute without giving the user permission to change it. It is an important part of encapsulation.

Example: If _minutes is an instance attribute in class Time, then the getter would be

```python
class Time(object):
    def getMinutes(self):
        """Return: _minutes attribute"""
        return self._minutes
```

Global Space. Global space is area of memory that stores any variable that is not defined in the body of a function. These variables include both function names and modules names, though it can include variables with more traditional values. Variables in global space remain until you explicitly erase them or until you quit Python.

Heap Space. Heap space is the area of memory that stores mutable objects (e.g. folders). It also stores function definitions, the contents of modules imported with the import command, as well as class folders. Folders in heap space remain until you explicitly erase them or until you quit Python. You cannot access heap space directly. You access them with variables in global space or in a call frame that contain the name of the object in heap space.

Immutable Attribute. An immutable attribute is a hidden attribute that has a getter, but no setter. This implies that a user it not allowed to alter the value of this attribute. It is an important part of encapsulation.

Implementation. The implementation of a collection of Python code (either a module or a class) are the details that are unimportant to other users of this module or class. It includes the bodies of all functions or methods, as well as all hidden attributes and functions or methods. These can be changed at any time, as long as they agree with the specifications and invariants present in the interface.

Inheritance. Inheritance is the process by which an object can have a method or attribute even if that method or attribute was not explicitly mentioned in the class definition. If the class is a subclass, then any method or attribute is inherited from the superclass.

Interface. The interface of a collection of Python code (either a module or a class) is the information that another user needs to know to use that module or class. It includes the list of all class names, the list of all unhidden attributes and their invariants, and the list of all unhidden functions/methods and their specifications. It does not include the body of any function or method, and any attributes that are hidden. The interface is the hardest part of your program to make changes to, because other people rely on it in order for their code to work correctly.
Invariant. An invariant is a statement about an attribute that must always be true. It can be like a precondition, in that prevents certain types of values from being assigned to the attribute. It can also be a relationship between multiple attributes, requiring that when one attribute is altered, the other attributes must be altered to match.

is. The is operator works like == except that it compares folder names, not contents. The meaning of the operator is can never be changed. This is different from ==, whose meaning is determined by the special operator method __eq__. If == is used on an object that does not have a definition for method __eq__, then == and is are the same.

Method. Methods are functions that are stored inside of an class folder. They are defined just like a function is defined, except that they are (indented) inside-of a class definition.

Example method toSeconds():

```python
class Time(object):
    # class with attributes minutes, hours
def toSeconds(self):
    return 60*self.hours+self.minutes
```

Methods are called by placing the object variable and a dot before the function name. The object before the dot is passed to the method definition as the argument self. Hence all method definitions must have at least one parameter.

Example: If t is a time object, then we call the method defined above with the syntax t.toSeconds(). The object t is passed to self.

Mutable Attribute. An mutable attribute is a hidden attribute that has both a getter and a setter. This implies that a user it allowed to alter the value of this attribute, provide that the invariant is not violated. It is an important part of encapsulation.

Object. An object is a value whose type is a class. Objects typically contain attributes, which are variables inside of the object which can potentially be modified. In addition, objects often have methods, which are functions that are stored inside of the object.

Operator Overloading. Operator overloading is the means by which Python evaluates the various operator symbols, such as +, *, /, and the like. The name refers to the fact that an operator can have many different “meanings” and the correct meaning depends on the type of the objects involved.

In this case, Python looks at the class or type of the object on the left. If it is a built-in type, it uses the built-in meaning for that type. Otherwise, it looks for the associated special method (beginning and ending with double underscores) in the class definition.

Overriding a Method. In a subclass, one can redefine a method that was defined in a superclass. This is called overriding the method. In general, the overriding method is called. To call an overridden method method of the superclass, use the notation

```python
<superclass>.method(self,...)
```

where <superclass> is the name of the parent class.
Property. A property is a special way of creating getters and setters. A property must have an associated attribute to work correctly, as the attribute is where it stores its value. The getter and setter are special methods that enforce the invariants for the property.

The getter and setter are each defined a method with the same name as the property. Python needs a decorator before the method to know it is the getter or setter. The decorator before a getter is @property. The decorator before a setter is @<property-name>.setter. The setter needs the property name its decorator because it is optional (the getter is not), and Python has to know which getter to associate it with.

Example property red in RGB:

```python
class RGB(object):
    _red = 0
    
    @property  # getter
    def red(self):
        return self._red

    @red.setter  # setter
    def red(self,value):
        assert type(value) == int
        assert 0 <= value and value <= 255
        self._red = value
```

In this example, _red is the (hidden) attribute associated with this property.

Not all getters and setters are properties. Properties are an advanced topic.

Setter. A setter is a special method that can change the value of an instance attribute (of the same name) when called. The purpose of the setter is to enforce any invariants. The docstring of the setter typically mentions the invariants as a precondition.

Example: If _minutes is an instance attribute in class Time, then the setter would be

```python
class Time(object):
    def setMinutes(self,value):
        """Set _minutes attribute to value

        Precondition: value is int in range 0..59"
        assert type(value) == int
        assert 0 <= value and value < 60
        self._minutes = value
```

Subclass. A subclass D is a class that extends another class C. This means that an instance of D inherits (has) all the attributes and methods that an instance of C has, in addition to the ones declared in D. In Python, every user-defined class must extend some other class. If you do not explicitly wish to extend another class, you should extend the built-in class called object (not to be confused with an object, which is an instance of a class). The built-in class object provides all of the special methods that begin and end with double underscores.
Try-Except Statement (Limited). A limited try-except statement is a try-except that only recovers for certain types of errors. It has the form

```
try:
    <statements>
except <error-class>:
    <statements>
```

Python executes all of the statements underneath try. If there is no error, then Python does nothing and skips over all the statements underneath except. However, if Python crashes while inside the try portion, it checks to see if the error object generated has class <error-class>. If so, it jumps to except, where it executes all the statements underneath there. Otherwise, the error propagates up the call stack where it might recover in another except statement or not at all.

**Example:**

```
try:
    print 'A'
    x = 1/0 print 'B'
except ZeroDivisionError:
    print 'C'
```

This code prints out 'A', but crashes when it divides 1/0. It skips over the remainder of the try (so it does not print out 'B'). Since the error is indeed a ZeroDivisionError, it jumps to the except and prints out 'C'.

Suppose, on the other hand, the try-except had been

```
try:
    print 'A'
    x = 1/0 print 'B'
except AssertionError:
    print 'C'
```

In this case, the code prints out 'A', but crashes when it divides 1/0 and does not recover.
