

Lecture 19: Graph Partitioning

David Bindel

5 Apr 2010

Logistics

- ▶ HW 3 due date: 4/9 (Friday) vs 4/19 (Monday)?
 - ▶ I accidentally added a “1” on the blurb page
 - ▶ But I want you working on your projects!
- ▶ HW 3 comments
 - ▶ Feel free to change interfaces
 - ▶ Can simplify identity preconditioner
 - ▶ Little luck with just a little parallelization

Graph partitioning

Given:

- ▶ Graph $G = (V, E)$
- ▶ Possibly weights (W_V, W_E) .
- ▶ Possibly coordinates for vertices (e.g. for meshes).

We want to partition G into k pieces such that

- ▶ Node weights are balanced across partitions.
- ▶ Weight of cut edges is minimized.

Important special case: $k = 2$.

Types of separators

- ▶ *Edge* separators: remove edges to partition
- ▶ *Node* separators: remove nodes (and adjacent edges)

Can go from one to the other.

Why partitioning?

- ▶ Physical network design (telephone layout, VLSI layout)
- ▶ Sparse matvec
- ▶ Preconditioners for PDE solvers
- ▶ Sparse Gaussian elimination
- ▶ Data clustering
- ▶ Image segmentation

Cost

How many partitionings are there? If n is even,

$$\binom{n}{n/2} = \frac{n!}{((n/2)!)^2} \approx 2^n \sqrt{2/(\pi n)}.$$

Finding the optimal one is NP-complete.

We need heuristics!

Partitioning with coordinates

- ▶ Lots of partitioning problems from “nice” meshes
 - ▶ Planar meshes (maybe with regularity condition)
 - ▶ k -ply meshes (works for $d > 2$)
 - ▶ Nice enough \implies partition with $O(n^{1-1/d})$ edge cuts (Tarjan, Lipton; Miller, Teng, Thurston, Vavasis)
 - ▶ Edges link nearby vertices
- ▶ Get useful information from vertex density
- ▶ Ignore edges (but can use them in later refinement)

Recursive coordinate bisection

Idea: Choose a cutting hyperplane parallel to a coordinate axis.

- ▶ Pro: Fast and simple
- ▶ Con: Not always great quality

Inertial bisection

Idea: Optimize cutting hyperplane based on vertex density

$$\bar{\mathbf{x}} = \frac{1}{n} \sum_{i=1}^n \mathbf{x}_i$$

$$\bar{\mathbf{r}}_i = \mathbf{x}_i - \bar{\mathbf{x}}$$

$$\mathbf{I} = \sum_{i=1}^n \left[\|\mathbf{r}_i\|^2 \mathbf{I} - \mathbf{r}_i \mathbf{r}_i^T \right]$$

Let (λ_n, \mathbf{n}) be the minimal eigenpair for the inertia tensor \mathbf{I} , and choose the hyperplane through $\bar{\mathbf{x}}$ with normal \mathbf{n} .

- ▶ Pro: Still simple, more flexible than coordinate planes
- ▶ Con: Still restricted to hyperplanes

Random circles (Gilbert, Miller, Teng)

- ▶ Stereographic projection
- ▶ Find centerpoint (any plane is an even partition)
In practice, use an approximation.
- ▶ Conformally map sphere, moving centerpoint to origin
- ▶ Choose great circle (at random)
- ▶ Undo stereographic projection
- ▶ Convert circle to separator

May choose best of several random great circles.

Coordinate-free methods

- ▶ Don't always have natural coordinates
 - ▶ Example: the web graph
 - ▶ Can sometimes add coordinates (metric embedding)
- ▶ So use edge information for geometry!

Breadth-first search

- ▶ Pick a start vertex v_0
 - ▶ Might start from several different vertices
- ▶ Use BFS to label nodes by distance from v_0
 - ▶ We've seen this before – remember RCM?
 - ▶ Could use a different order – minimize edge cuts locally (Karypis, Kumar)
- ▶ Partition by distance from v_0

Greedy refinement

Start with a partition $V = A \cup B$ and refine.

- ▶ Gain from swapping (a, b) is $D(a) + D(b)$, where

$$D(a) = \sum_{b' \in B} w(a, b') - \sum_{a' \in A, a' \neq a} w(a, a')$$

$$D(b) = \sum_{a' \in A} w(b, a') - \sum_{b' \in B, b' \neq b} w(b, b')$$

- ▶ Purely greedy strategy:
 - ▶ Choose swap with most gain
 - ▶ Repeat until no positive gain
- ▶ Local minima are a problem.

Kernighan-Lin

In one sweep:

While no vertices marked

 Choose (a, b) with greatest gain

 Update $D(v)$ for all unmarked v as if (a, b) were swapped

 Mark a and b (but don't swap)

Find j such that swaps $1, \dots, j$ yield maximal gain

Apply swaps $1, \dots, j$

Usually converges in a few (2-6) sweeps. Each sweep is $O(N^3)$.

Can be improved to $O(|E|)$ (Fiduccia, Mattheyses).

Further improvements (Karypis, Kumar): only consider vertices on boundary, don't complete full sweep.

Spectral partitioning

Label vertex i with $x_i = \pm 1$. We want to minimize

$$\text{edges cut} = \frac{1}{4} \sum_{(i,j) \in E} (x_i - x_j)^2$$

subject to the even partition requirement

$$\sum_i x_i = 0.$$

But this is NP hard, so we need a trick.

Spectral partitioning

Write

$$\text{edges cut} = \frac{1}{4} \sum_{(i,j) \in E} (x_i - x_j)^2 = \frac{1}{4} \|Cx\|^2 = \frac{1}{4} x^T Lx$$

where C is the incidence matrix and $L = C^T C$ is the graph Laplacian:

$$C_{ij} = \begin{cases} 1, & e_j = (i, k) \\ -1, & e_j = (k, i) \\ 0, & \text{otherwise,} \end{cases} \quad L_{ij} = \begin{cases} d(i), & i = j \\ -1, & i \neq j, (i, j) \in E, \\ 0, & \text{otherwise.} \end{cases}$$

Note that $Ce = 0$ (so $Le = 0$), $e = (1, 1, 1, \dots, 1)^T$.

Spectral partitioning

Now consider the *relaxed* problem with $x \in \mathbb{R}^n$:

$$\text{minimize } x^T L x \text{ s.t. } x^T e = 0 \text{ and } x^T x = 1.$$

Equivalent to finding the second-smallest eigenvalue λ_2 and corresponding eigenvector x , also called the *Fiedler vector*.
Partition according to sign of x_i .

How to approximate x ? Use a Krylov subspace method (Lanczos)!
Expensive, but gives high-quality partitions.

Multilevel ideas

Basic idea (same will work in other contexts):

- ▶ Coarsen
- ▶ Solve coarse problem
- ▶ Interpolate (and possibly refine)

May apply recursively.

Maximal matching

One idea for coarsening: maximal matchings

- ▶ *Matching* of $G = (V, E)$ is $E_m \subset E$ with no common vertices.
- ▶ *Maximal* if no more edges can be added and remain matching.
- ▶ Constructed by an obvious greedy algorithm.
- ▶ Maximal matchings are non-unique; some may be preferable to others (e.g. choose heavy edges first).

Coarsening via maximal matching

- ▶ Collapse nodes connected in matching into coarse nodes
- ▶ Add all edge weights between connected coarse nodes

Software

All these use some flavor(s) of multilevel:

- ▶ METIS/ParMETIS (Kapyris)
- ▶ Chaco (Sandia)
- ▶ Scotch (INRIA)
- ▶ Jostle (now commercialized)
- ▶ Zoltan (Sandia)

Is this it?

Consider partitioning for sparse matvec:

- ▶ Edge cuts \neq communication volume
- ▶ Haven't looked at minimizing *maximum* communication volume
- ▶ Looked at communication volume – what about latencies?

Some work beyond graph partitioning (e.g. in Zoltan).
