Search is a central topic in AI.

Originated with Newell and Simon’s work on problem solving; Human Problem Solving (1972).

Automated reasoning is a natural search task.

More recently: Given that almost all AI formalisms (planning, learning, etc) are NP-Complete or worse, some form of search (or optimization) is generally unavoidable (i.e., no smarter algorithm available).
Outline

Problem-solving agents
Problem types
Problem formulation
Example problems
Basic search algorithms
Problem-solving agents

Problem solving agents are goal-directed agents:

1. **Goal Formulation:** Set of one or more (desirable) world states (e.g. checkmate in chess).
2. **Problem formulation:** What actions and states to consider given a goal and an initial state.
3. **Search for solution:** Given the problem, search for a solution --- *a sequence of actions to achieve the goal starting from the initial state.*
4. **Execution of the solution**

Note: Formulation may feel somewhat “contrived,” but was meant to model very general (human) problem solving process.
Example: Path Finding problem

Formulate goal:
- be in Bucharest (Romania)

Formulate problem:
- action: drive between pair of connected cities (direct road)
- state: be in a city (20 world states)

Find solution:
- sequence of cities leading from start to goal state, e.g., Arad, Sibiu, Fagaras, Bucharest

Execution
- drive from Arad to Bucharest according to the solution

Environment: fully observable (map), deterministic, and the agent knows effects of each action. Is this really the case?

Note: Map is somewhat of a “toy” example. Our real interest: Exponentially large spaces, with e.g. $10^{100}$ or more states. Far beyond full search. Humans can often still handle those! (We need to define a distance measure.) One of the mysteries of cognition.
Micro-world: The Blocks World

How many different possible world states?

(a) “Pick up a big red block.”

(b) “Find a block which is taller than the one you are holding and put it into the box.”

(c) “Will you please stack up both of the red blocks and either a green cube or a pyramid?”

a) Tens?
b) Hundreds?
c) Thousands?
d) Millions?
e) Billions?
f) Trillions?
Size state space of blocks world example

**n = 8 objects, k = 9 locations to build towers, one gripper. (One location in box.)**
All objects distinguishable, order matter in towers. (Assume stackable in any order.)

Blocks: Use r-combinations approach from Rosen (section 5.5; CS-2800).

- - - - - - - - - - - - - - - -
consider 16 = (n + k – 1) “spots”
Select k – 1 = 8 “dividers” to create locations,
(16 choose 8) ways to do this, e.g.,

| | - - - | - | - - - | - |
Allocate n = 8 objs to remaining spots, 8! ways, e.g.,

| 4 1 8 | 5 | 6 3 7 | 2 |
d based on dividers

So, total number of states (ignoring gripper): (16 choose 8) * 8! = 518,918,400

* 9 for location gripper: > 4.5 billion states even in this toy domain!

Search spaces grow exponentially with domain. **Still need to search them, e.g., to find a sequence of states (via gripper moves) leading to a desired goal state.**

How do we represent states? [predicates / features]
1) Deterministic, fully observable
Agent knows exactly which state it will be in; solution is a sequence of actions.

2) Non-observable --- sensorless problem
   - Agent may have no idea where it is (no sensors); it reasons in terms of belief states; solution is a sequence actions (effects of actions certain).

3) Nondeterministic and/or partially observable: contingency problem
   - Actions uncertain, percepts provide new information about current state (adversarial problem if uncertainty comes from other agents).
   - Solution is a “strategy” to reach the goal.

4) Unknown state space and uncertain action effects: exploration problem
   -- Solution is a “strategy” to reach the goal (end explore environment).
Example: Vacuum world state space graph

Start state

Goal
(reach one in this set of states)

- **states?** The agent is in one of 8 possible world states.
- **actions?** *Left, Right, Suck [simplified: left out No-op]*
- **goal test?** No dirt at all locations (i.e., in one of bottom two states).
- **path cost?** 1 per action

Minimum path from Start to Goal state: **3 actions**
Alternative, longer plan: **4 actions**

Note: path with thousands of steps before reaching goal also exists.
Example: The 8-puzzle “sliding tile puzzle”

- **states?** the boards, i.e., locations of tiles
- **actions?** move blank left, right, up, down
- **goal test?** goal state (given; tiles in order)
- **path cost?** 1 per move

Note: finding **optimal** solution of $n$-puzzle family is NP-hard!
Also, from certain states you can’t reach the goal.
Total number of states $9! = 362,880$ (more interesting space; not all connected… only half can reach goal state)

Aside: variations on goal state.
eg empty square bottom right or in middle.
15-puzzle

Search space: \(16!/2 = 1.0461395 \times 10^{13}\), about 10 trillion. Too large to store in RAM (\(\geq 100\) TB). A challenge to search for a path from a given board to goal.

Korf: Disk errors become a problem.

Longest minimum path: 80 moves. Just 17 boards, e.g,

Average minimum soln. length: 53.

People can find solns. But not necessarily minimum length. See solve it! (Gives strategy.)

Where are the 10 trillion states?

minimum distance from goal state (# moves)

<table>
<thead>
<tr>
<th>dist.</th>
<th># states</th>
</tr>
</thead>
<tbody>

</tbody>
</table>

etc.
17 boards farthest away from goal state (80 moves)

Each require 80 moves to reach:

Intriguing similarities. Each number has its own few locations.

Interesting machine learning task:
Learn to recognize the hardest boards!

(Extremal Combinatorics, e.g. LeBras, Gomes, and Selman AAAI-12)
17 boards farthest away from goal state (80 moves)

Most regular extreme case:

Each quadrant reflected along diagonal. “move tiles furthest away”

Goal state

Thanks to Jonathan GS
A few urls:

* Play the eight puzzle on-line
* Play the fifteen puzzle on-line

Let’s consider the search for a solution.
Searching for a solution to the 8-puzzle.

A breadth-first search tree. (More detail soon.)

Aside: in this tree, immediate duplicates are removed.

Branching factor 1, 2, or 3 (max). So, approx. 2 --- # nodes roughly doubles at each level. *Number states of explored nodes grows exponentially with depth.*
For 15-puzzle, hard initial states: 80 levels deep, requires exploring approx. $2^{80} \approx 10^{24}$ states.

If we block all duplicates, we get closer to 10 trillion (the number of distinct states: still a lot!).

Really only barely feasible on compute cluster with lots of memory and compute time. (Raw numbers for 24 puzzle, truly infeasible.)

Can we avoid generating all these boards? Do with much less search? (Key: bring average branching factor down.)
Gedanken experiment: Assume that you knew for each state, the minimum number of moves to the final goal state. (Table too big, but assume there is some formula/algorithm based on the board pattern that gives this number for each board and quickly.)

Using the minimum distance information, is there a clever way to find a minimum length sequence of moves leading from the start state to the goal state? What is the algorithmic strategy?
Hmm. How do I know?

Note: at least one neighbor with $d = 4$.

A breadth-first search tree. (More detail soon.)

Branching factor approx. 2. So, with “distance oracle” we only need to explore approx. $2 \times (\text{min. solution length})$. (Why 2 times?)
For 15-puzzle, hard initial states: 80 levels deep, requires exploring approx. $2^{80} \approx 10^{24}$ states.

But, with distance oracle, we only need to explore roughly $80 \times 2 = 160$ states! (only linear in size of solution length)

We may not have the exact distance function ("perfect heuristics"), but we can still "guide" the search using an approximate distance function.

This is the key idea behind "heuristic search" or "knowledge-based search." We use knowledge / heuristic information about the distance to the goal to guide our search process. We can go from exponential to polynomial or even linear complexity. More common: brings exponent down significantly. E.g. from $2^L$ to $2^{(L/100)}$.

The measure we considered would be the "perfect" heuristic. Eliminates tree search! Find the right "path" to goal state immediately.
Basic idea: State evaluation function can effectively guide search.

Also in multi-agent settings. (Chess: board eval.)

Reinforcement learning: Learn the state eval function.

A breadth-first search tree.

Perfect “heuristics,” eliminates search.

Approximate heuristics, significantly reduces search.

Best (provably) use of search heuristic info: A* search (soon).

General question: Given a state space, how good a heuristics can we find?
State evaluation functions or “heuristics”

Provide guidance in terms of what action to take next.

General principle: Consider all neighboring states, reachable via some action. Then select the action that leads to the state with the highest utility (evaluation value). This is a fully greedy approach.

Aside: “Highest utility” was “shortest distance to the goal” in previous example.

Because eval function is often only an estimate of the true state value, greedy search may not find the optimum path to the goal.

By adding some search with certain guarantees on the approximation, we can still get optimal behavior (A* search) (i.e. finding the optimal path to the solution). Overall result: generally exponentially less search required.
N-puzzle heuristics ("State evaluation function" wrt the goal to be reached):

1) **Manhattan Distance:** For each tile the number of grid units between its current location and its goal location are counted and the values for all tiles are summed up. (underestimate; too “loose”; not very powerful)

2) **Felner, Ariel, Korf, Richard E., Hanan, Sarit, Additive Pattern Database Heuristics,** Journal of Artificial Intelligence Research 22 (2004) 279-318. The 78 Pattern Database heuristic takes a lot of memory but solves a random instance of the 15-puzzle within a few milliseconds on average. An optimal solution for the 80 moves cases takes a few seconds each. So, thousands of nodes considered instead of many billions.

Note: many approx. heuristics ("conservative" / underestimates to goal) combined with search can still find optimal solutions.
State evaluation function (or utility value) is a very general and useful idea.

Example:

- In chess, given a board, what would be the perfect evaluation value that you would want to know? (Assume the perspective of White player.)

A: \( f(\text{board}) \rightarrow \{+1, 0, -1\} \), with +1 for guaranteed win for White, 0 draw under perfect play, and -1 loss under perfect play.

Perfect play: all powerful opponent.

Given \( f \), how would you play then?

In practice, we only know (so far) of an approximation of \( f \).

\( f(\text{board}) \rightarrow [-1,+1] \) (interval from -1 to +1)

based on “values” of chess pieces, e.g., pawn 1 point, rook 5 points.

Informally, board value gives “probability (?) of winning.”
State evaluation function (or utility value) is a very general and useful idea.

Examples:

• TD-Gammon backgammon player. Neural net was trained to find approximately optimal state (board) evaluation values (range [-1,+1]). (Tesauro 1995)

• “Robocopter” --- automated helicopter control; trained state evaluation function. State given by features, such as, position, orientation, speed, and rotors position and speed. Possible actions change rotors speed and position. Evaluation assigns value in [-1,+1] to capture stability. (Abbeel, Coates, and Ng 2008)
Example: Robotic assembly

**states?**: real-valued coordinates of robot joint angles

**parts of the object to be assembled**

**actions?**: continuous motions of robot joints

**goal test?**: complete assembly

**path cost?**: time to execute
Other example search tasks

VLSI layout: positioning millions of components and connections on a chip to minimize area, circuit delays, etc.

Robot navigation / planning

Automatic assembly of complex objects

Protein design: sequence of amino acids that will fold into the 3-dimensional protein with the right properties.

Literally thousands of combinatorial search / reasoning / parsing / matching problems can be formulated as search problems in exponential size state spaces.
Search Techniques
Searching for a (shortest / least cost) path to goal state(s).

Search through the state space.

We will consider search techniques that use an explicit search tree that is generated by the initial state + successor function.

initialize (initial node)
Loop
  choose a node for expansion according to strategy
  goal node? → done
  expand node with successor function
Tree-search algorithms

Basic idea:

- simulated exploration of state space by generating successors of already-explored states (a.k.a. ~ expanding states)

```python
function TREE-SEARCH(problem, strategy) returns a solution, or failure
    initialize the search tree using the initial state of problem
    loop do
        if there are no candidates for expansion then return failure
        choose a leaf node for expansion according to strategy
        if the node contains a goal state then return the corresponding solution
        else expand the node and add the resulting nodes to the search tree
    end loop
```

Fig. 3.7 R&N, p. 77

Note: 1) Here we only check a node for possibly being a goal state, after we select the node for expansion.
2) A “node” is a data structure containing state + additional info (parent node, etc.)
Node selected for expansion.
Nodes added to tree.
Selected for expansion.

Note: Arad added (again) to tree! (reachable from Sibiu)

Not necessarily a problem, but in Graph-Search, we will avoid this by maintaining an “explored” list.
function GRAPH-SEARCH(problem) returns a solution, or failure
initialize the frontier using the initial state of problem
initialize the explored set to be empty
loop do
  if the frontier is empty then return failure
  choose a leaf node and remove it from the frontier
  if the node contains a goal state then return the corresponding solution
  add the node to the explored set
  expand the chosen node, adding the resulting nodes to the frontier
    only if not in the frontier or explored set

Fig. 3.7 R&N, p. 77. See also exercise 3.13.

Note:
1) Uses “explored” set to avoid visiting already explored states.
2) Uses “frontier” set to store states that remain to be explored and expanded.
3) However, with eg uniform cost search, we need to make a special check when node (i.e. state) is on frontier. Details later.
Implementation: states vs. nodes

A state is a --- representation of --- a physical configuration.

A node is a data structure constituting part of a search tree includes state, tree parent node, action (applied to parent), path cost (initial state to node) $g(x)$, depth

The `Expand` function creates new nodes, filling in the various fields and using the `SuccessorFn` of the problem to create the corresponding states.

Fringe is the collection of nodes that have been generated but not (yet) expanded. Each node of the fringe is a leaf node.
Implementation: general tree search

function Tree-Search( problem, fringe) returns a solution, or failure
  fringe ← Insert(Make-Node(Initial-State[problem]), fringe)
  loop do
    if fringe is empty then return failure
    node ← Remove-Front(fringe)
    if Goal-Test[problem](State[node]) then return Solution(node)
    fringe ← InsertAll(Expand(node, problem), fringe)

function Expand( node, problem) returns a set of nodes
  successors ← the empty set
  for each action, result in Successor-Fn[problem](State[node]) do
    s ← a new Node
    Parent-Node[s] ← node; Action[s] ← action; State[s] ← result
    Path-Cost[s] ← Path-Cost[node] + Step-Cost(node, action, s)
    Depth[s] ← Depth[node] + 1
    add s to successors
  return successors
A search strategy is defined by picking the order of node expansion.

Strategies are evaluated along the following dimensions:

- **completeness**: does it always find a solution if one exists?
- **time complexity**: number of nodes generated
- **space complexity**: maximum number of nodes in memory
- **optimality**: does it always find a least-cost solution?

Time and space complexity are measured in terms of

- $b$: maximum branching factor of the search tree
- $d$: depth of the least-cost solution
- $m$: maximum depth of the state space (may be $\infty$)
Uninformed (blind) search strategies use only the information available in the problem definition:

- Breadth-first search
- Uniform-cost search
- Depth-first search
- Depth-limited search
- Iterative deepening search
- Bidirectional search

**Key issue:** type of queue used for the fringe of the search tree (collection of tree nodes that have been generated but not yet expanded)
Breadth-first search

Expand shallowest unexpanded node.

**Implementation:**
- *fringe* is a FIFO queue, i.e., new nodes go at end (First In First Out queue.)

```
Fringe queue:  <A>
```

Select A from queue and expand.

Gives <B, C>
Queue: <B, C>

Select B from front, and expand.

Put children at the end.

Gives <C, D, E>
Fringe queue: <C, D, E>
Fringe queue:  <D, E, F, G>

Properties of breadth-first search

**Complete?** Yes (if \( b \) is finite)

**Time?** \( 1 + b + b^2 + b^3 + \ldots + b^d + b(b^d - 1) = O(b^{d+1}) \)

**Space?** \( O(b^{d+1}) \) (keeps every node in memory; needed also to reconstruct soln. path)

**Optimal soln. found?** Yes (if all step costs are identical)

**Space is the bigger problem (more than time)**

- \( b \): maximum branching factor of the search tree
- \( d \): depth of the least-cost solution
Uniform-cost search

Expand **least-cost** (of path to) unexpanded node
   (e.g. useful for finding shortest path on map)

**Implementation:**
   - fringe = queue *ordered by path cost*

**Complete?** Yes, if step cost $\geq \varepsilon$ (>0)

**Time?** # of nodes with $g \leq$ cost of optimal solution ($C^*$),
   \[ O(b^{1+\lceil C^*/\varepsilon \rceil}) \]

**Space?** # of nodes with $g \leq$ cost of optimal solution,
   \[ O(b^{1+\lceil C^*/\varepsilon \rceil}) \]

**Optimal?** Yes – nodes expanded in increasing order of $g(n)$

*Note: Some subtleties (e.g. checking for goal state).*

See p 84 R&N. Also, next slide.
Uniform-cost search

Two subtleties: (bottom p. 83 Norvig)
1) Do goal state test, only when a node is selected for expansion.  
   *(Reason: Bucharest may occur on frontier with a longer than optimal path. It won’t be selected for expansion yet. Other nodes will be expanded first, leading us to uncover a shorter path to Bucharest. See also point 2).*

2) Graph-search alg. says “don’t add child node to frontier if already on explored list or already on frontier.” BUT, child may give a shorter path to a state already on frontier. Then, we need to modify the existing node on frontier with the shorter path. See fig. 3.14 (else-if part).
Depth-first search

“Expand deepest unexpanded node”

Implementation:
- fringe = LIFO queue, i.e., put successors at front (“push on stack”)
  Last In First Out

Fringe stack: A
Expanding A, gives stack: B, C
So, B next.
Expanding B, gives stack:

D
E
C

So, D next.
Expanding D, gives stack:
H
I
E
C
So, H next.

etc.
What is main advantage over breadth first search?

What information is stored? How much storage required?

The stack. $O(\text{depth} \times \text{branching})$. 
Properties of depth-first search

**Complete?** No: fails in infinite-depth spaces, spaces with loops
  Modify to avoid repeated states along path
  → complete in finite spaces

**Time?** \( O(b^m) \): bad if \( m \) is much larger than \( d \)
  – but if solutions are dense, may be much faster than breadth-first

**Space?** \( O(bm) \), i.e., linear space!

**Guarantee that opt. soln. is found?** No

\( b \): max. branching factor of the search tree
\( d \): depth of the shallowest (least-cost) soln.
\( m \): maximum depth of state space

Note: In “backtrack search” only one successor is generated
  → only \( O(m) \) memory is needed; also successor is modification of the current state, but we have to be able to undo each modification.
More when we talk about Constraint Satisfaction Problems (CSP).
Iterative deepening search

function iterative-deepening-search(problem) returns a solution, or failure

- inputs: problem, a problem

  for depth ← 0 to ∞ do
    result ← depth-limited-search(problem, depth)
    if result ≠ cutoff then return result
Iterative deepening search $l = 0$
Iterative deepening search $l = 1$
Iterative deepening search $l=2$

Limit = 2

Diagram showing the iterative deepening search process with a limit of 2.
Iterative deepening search $l = 3$
Why would one do that?

Combine **good memory requirements** of depth-first with the **completeness** of breadth-first when branching factor is finite and is **optimal** when the path cost is a non-decreasing function of the depth of the node.

Idea was a breakthrough in game playing. All game tree search uses iterative deepening nowadays. What’s the added advantage in games?

“**Anytime**” nature.
Iterative deepening search

Number of nodes generated in an iterative deepening search to depth \( d \) with branching factor \( b \):

Looks quite wasteful, is it?

\[
N_{\text{IDS}} = db^1 + (d-1)b^2 + \ldots + 3b^{d-2} + 2b^{d-1} + 1b^d
\]

Nodes generated in a breadth-first search with branching factor \( b \):

\[
N_{\text{BFS}} = b^1 + b^2 + \ldots + b^{d-2} + b^{d-1} + b^d
\]

For \( b = 10 \), \( d = 5 \),

\[
- \quad N_{\text{BFS}} = 10 + 100 + 1,000 + 10,000 + 100,000 = 111,110
\]

\[
- \quad N_{\text{IDS}} = 50 + 400 + 3,000 + 20,000 + 100,000 = 123,456
\]

Iterative deepening is the preferred uninformed search method when there is a large search space and the depth of the solution is not known.
Properties of iterative deepening search

**Complete?** Yes

(b finite)

**Time?** $d b^1 + (d-1)b^2 + \ldots + b^d = O(b^d)$

**Space?** $O(bd)$

**Optimal?** Yes, if step costs identical
Bidirectional Search

Simultaneously:
- Search forward from start
- Search backward from the goal
Stop when the two searches meet.

If branching factor = b in each direction, with solution at depth d
then only $O(2^{b^{d/2}}) = O(2^{b^{d/2}})$

Checking a node for membership in the other search tree can be done in constant time (hash table)

Key limitations:
Space $O(b^{d/2})$
Also, how to search backwards can be an issue (e.g., in Chess)? What’s tricky?
Problem: lots of states satisfy the goal; don’t know which one is relevant.

Aside: The predecessor of a node should be easily computable (i.e., actions are easily reversible).
Failure to detect repeated states can turn linear problem into an exponential one!

Problems in which actions are reversible (e.g., routing problems or sliding-blocks puzzle). Also, in eg Chess; uses hash tables to check for repeated states. Huge tables 100M+ size but very useful.

See Tree-Search vs. Graph-Search in Fig. 3.7 R&N. But need to be careful to maintain (path) optimality and completeness.
Original search ideas in AI where inspired by studies of human problem solving in, eg, puzzles, math, and games, but a great many AI tasks now require some form of search (e.g. find optimal agent strategy; active learning; constraint reasoning; NP-complete problems require search).

Problem formulation usually requires abstracting away real-world details to define a state space that can feasibly be explored.

Variety of uninformed search strategies

Iterative deepening search uses only linear space and not much more time than other uninformed algorithms.

Avoid repeating states / cycles.
