## Abstract

The topology of a wireless multi-hop network can be controlled by varying the transmission power at each node. In this paper, we give a detailed analysis of a cone-based distributed topology control algorithm. This algorithm does not assume that nodes have GPS information available; rather it depends only on directional information. Roughly speaking, the basic idea of the algorithm is that a node  $u$  transmits with the minimum power  $p_{u,\alpha}$  required to ensure that in every cone of degree  $\alpha$  around  $u$ , there is some node that  $u$  can reach with power  $p_{u,\alpha}$ . We show that taking  $\alpha = 5\pi/6$  is a necessary and sufficient condition to guarantee that network connectivity is preserved. More precisely, if there is a path from  $s$  to  $t$  when every node communicates at maximum power then, if  $\alpha \leq 5\pi/6$ , there is still a path in the smallest symmetric graph  $G_\alpha$  containing all edges  $(u, v)$  such that  $u$  can communicate with  $v$  using power  $p_{u,\alpha}$ . On the other hand, if  $\alpha > 5\pi/6$ ,

---

\*This is a revised and extended version of “Analysis of a cone-based topology control algorithm for wireless multi-hop networks”, which appeared in *Proceedings of ACM Principles of Distributed Computing (PODC)*, 2001, and includes results from “Distributed topology control for power efficient operation in multihop wireless ad hoc networks”, by R. Wattenhofer, L. Li, P. Bahl, and Y. M. Wang, which appeared in *Proceedings of IEEE INFOCOM*, 2001.

connectivity is not necessarily preserved. We also propose a set of optimizations that further reduce power consumption and prove that they retain network connectivity. Dynamic reconfiguration in the presence of failures and mobility is also discussed. Simulation results are presented to demonstrate the effectiveness of the algorithm and the optimizations.

## 1 Introduction

Multi-hop wireless networks, such as radio networks [11], ad-hoc networks [16], and sensor networks [4, 18], are networks where communication between two nodes may go through multiple consecutive wireless links. Unlike wired networks, which typically have a fixed network topology (except in case of failures), each node in a wireless network can potentially change the network topology by adjusting its transmission power to control its set of neighbors. The primary goal of topology control is to design power-efficient algorithms that maintain network connectivity and optimize performance metrics such as network lifetime and throughput. As pointed out by Chandrakasan et. al [2], network protocols that minimize energy consumption are key to the successful usage of wireless sensor networks. To simplify deployment and reconfiguration in the presence of failures and mobility, distributed topology control algorithms that utilize only local information and allow asynchronous operations are particularly attractive.

The topology control problem can be formalized as follows. We are given a set  $V$  of possibly mobile nodes located in the plane. Each node  $u \in V$  is specified by its coordinates,  $(x(u), y(u))$ , at any given point in time. Each node  $u$  has a power function  $p$  where  $p(d)$  gives the minimum power needed to establish a communication link to a node  $v$  at distance  $d$  away from  $u$ . Assume that the maximum transmission power  $P$  is the same for every node, and the maximum distance for any two nodes to communicate directly is  $R$ , i.e.  $p(R) = P$ . If every node transmits with power  $P$ , then we have an induced graph  $G_R = (V, E)$  where  $E = \{(u, v) | d(u, v) \leq R\}$  (where  $d(u, v)$  is the Euclidean distance between  $u$  and  $v$ ).

It is undesirable to have nodes transmit with maximum power for two reasons. First, since the power required to transmit between nodes increases as the  $n$ th power of the distance between them, for some  $n \geq 2$  [21], it may require less power for a node  $u$  to relay messages through a series of intermediate nodes to  $v$  than to transmit directly to  $v$ . Second, the greater the power with which a node transmits, the greater the likelihood of the transmission interfering with other transmissions.

Our goal in performing topology control is to find a subgraph  $G$  of  $G_R$  such that (1)  $G$  consists of all the nodes in  $G_R$  but has fewer edges, (2) if  $u$  and  $v$  are connected in  $G_R$ , they are still connected in  $G$ , and (3) a node  $u$  can transmit to all its neighbors in  $G$  using less power than is required to transmit to all its neighbors in  $G_R$ . Since minimizing power consumption is so important, it is desirable to find a graph  $G$  satisfying these three properties that minimizes the amount of power that a node needs to use to communicate

with all its neighbors. Furthermore, for a topology control algorithm to be useful in practice, it must be possible for each node  $u$  in the network to construct its neighbor set  $N(u) = \{v | (u, v) \in G\}$  in a distributed fashion. Finally, if  $G_R$  changes to  $G'_R$  due to node failures or mobility, it must be possible to reconstruct a connected  $G'$  without global coordination.

In this paper we consider a cone-based topology-control algorithm, and show that it satisfies all these desiderata. Most previous papers on topology control have utilized position information, which usually requires the availability of GPS at each node. There are a number of disadvantages with using GPS. In particular, the acquisition of GPS location information incurs a high delay, and GPS does not work in indoor environments or cities. By way of contrast, the cone-based algorithm requires only the availability of directional information. That is, it must be possible to estimate the direction from which another node is transmitting. Techniques for estimating direction without requiring position information are available, and discussed in the IEEE antenna and propagation community as the Angle-of-Arrival problem. The standard way of doing this is by using more than one directional antenna (see [13]). Specifically, the direction of incoming signals is determined from the difference in their arrival times at different elements of the antenna.<sup>1</sup>

The cone-based algorithm takes as a parameter an angle  $\alpha$ . A node  $u$  then tries to find the minimum power  $p_{u,\alpha}$  such that transmitting with  $p_{u,\alpha}$  ensures that in every cone of degree  $\alpha$  around  $u$ , there is some node that  $u$  can reach. We show that taking  $\alpha = 5\pi/6$  is necessary and sufficient to preserve connectivity. That is, we show that if  $\alpha \leq 5\pi/6$ , then there is a path from  $u$  to  $v$  in  $G_R$  iff there is such a path in  $G_\alpha$  (for all possible node locations) and that if  $\alpha > 5\pi/6$ , then there exists a graph  $G_R$  that is connected while  $G_\alpha$  is not. Moreover, we propose several optimizations and show that they preserve connectivity. Finally, we discuss how the algorithm can be extended to deal with dynamic reconfiguration and asynchronous operations.

There are a number of other papers in the literature on topology control; as we said earlier, all assume that position information is available. Hu [9] describes an algorithm that does topology control using heuristics based on a Delauney triangulation of the graph. There seems to be no guarantee that the heuristics preserve connectivity. Ramanathan and Rosales-Hain [20] describe a centralized spanning tree algorithm for achieving connected and biconnected static networks, while minimizing the maximum transmission power. (They also describe distributed algorithms that are based on heuristics and are not guaranteed to preserve connectivity.) Rodoplu and Meng [22] propose a distributed position-based topology control algorithm that preserves connectivity; their algorithm is improved by Li and Halpern [14]. Other researchers working in the field of packet radio networks, wireless ad hoc networks, and sensor networks have also considered the issue of power efficiency and network lifetime, but have taken different approaches.

---

<sup>1</sup>Of course, if GPS information is available, a node can simply piggyback its location to its message and the required directional information can be calculated from that.

For example, Hou and Li [8] analyze the effect of adjusting transmission power to reduce interference and hence achieve higher throughput as compared to schemes that use fixed transmission power [23]. Heinzelman et al. [7] describe an adaptive clustering-based routing protocol that maximizes network lifetime by randomly rotating the role of per-cluster local base stations (cluster-head) among nodes with higher energy reserves. Chen et al. [3] and Xu et al. [27] propose methods to conserve energy and increase network lifetime by turning off redundant nodes. Finally, Wu et al. [26] and Monks et al. [26, 15] describe their power controlled MAC protocols to reduce energy consumptions and increase throughput. They do this through power control of unicast packets, but make no attempt at reducing the power consumption of broadcast packets. In a different vein is the work described in [6, 12]; although it does not deal directly with topology control, the notion of  $\theta$ -graph used in these papers bears some resemblance to the cone-based idea described in this paper. Relative neighborhood graphs [24] and their relatives (such as Gabriel graphs, or  $G_\beta$  graphs [10]) are similar in spirit to the graphs produced by the cone-based algorithm.

The rest of the paper is organized as follows. Section 2 presents the basic cone-based algorithm and shows that  $\alpha = 5\pi/6$  is necessary and sufficient for connectivity. Section 3 describes several optimizations to the basic algorithm and proves their correctness. Section 4 extends the basic algorithm so that it can handle the reconfiguration necessary to deal with failures and mobility. Section 5 describes network simulation results that show the effectiveness of the basic approach and the optimizations. Section 6 summarizes this paper.

## 2 The Basic Cone-Based Topology Control Algorithm

We consider three communication primitives: broadcast, send, and receive, defined as follows:

- $bcast(u, p, m)$  is invoked by node  $u$  to send message  $m$  with power  $p$ ; it results in all nodes in the set  $\{v | p(d(u, v)) \leq p\}$  receiving  $m$ .
- $send(u, p, m, v)$  is invoked by node  $u$  to send message  $m$  to  $v$  with power  $p$ . This primitive is used to send unicast messages, i.e. point-to-point messages.
- $recv(u, m, v)$  is used by  $u$  to receive message  $m$  from  $v$ .

We assume that when  $v$  receives a message  $m$  from  $u$ , it knows the reception power  $p'$  of message  $m$ . This is, in general, less than the power  $p$  with which  $u$  sent the message, because of radio signal attenuation in space. Moreover, we assume that, given the transmission power  $p$  and the reception power  $p'$ ,  $u$  can estimate  $p(d(u, v))$ . This assumption is reasonable in practice.

For ease of presentation, we first assume a synchronous model; that is, we assume that communication proceeds in rounds, governed by a global clock, with each round taking one time unit. (We deal with asynchrony in Section 4.) In each round each node  $u$  can examine the messages sent to it, compute, and send messages using the *bcast* and *send* communication primitives. The communication channel is reliable. We later relax this assumption, and show that the algorithm is correct even in an asynchronous setting.

The basic Cone-Based Topology-Control (*CBTC*) algorithm is easy to explain. The algorithm takes as a parameter an angle  $\alpha$ . Each node  $u$  tries to find at least one neighbor in every cone of degree  $\alpha$  centered at  $u$ . Node  $u$  starts running the algorithm by broadcasting a “Hello” message using low transmission power, and collecting Ack replies. It gradually increases the transmission power to discover more neighbors. It keeps a list of the nodes that it has discovered and the direction in which they are located. (As we said in the introduction, we assume that each node can estimate directional information.) It then checks whether each cone of degree  $\alpha$  contains a node. This check is easily performed: the nodes are sorted according to their angles relative to some reference node (say, the first node from which  $u$  received a reply). It is immediate that there is a gap of more than  $\alpha$  between the angles of two consecutive nodes iff there is a cone of degree  $\alpha$  centered at  $u$  which contains no nodes. If there is such a gap, then  $u$  broadcasts with greater power. This continues until either  $u$  finds no  $\alpha$ -gap or  $u$  broadcasts with maximum power.

Figure 1 gives the basic CBTC algorithm. In the algorithm, a “Hello” message is originally broadcasted using some minimal power  $p_0$ . In addition, the power used to broadcast the message is included in the message. The power is then increased at each step using some function *Increase*. As in [14] (where a similar function is used, in the context of a different algorithm), in this paper, we do not investigate how to choose the initial power  $p_0$ , nor do we investigate how to increase the power at each step. We simply assume some function *Increase* such that  $\text{Increase}^k(p_0) = P$  for sufficiently large  $k$ . As observed in [14], an obvious choice is to take  $\text{Increase}(p) = 2p$ . If the initial choice of  $p_0$  is less than the total power actually needed, then it is easy to see that this guarantees that  $u$ 's estimate of the transmission power needed to reach a node  $v$  will be within a factor of 2 of the minimum transmission power actually needed to reach  $v$ .

Upon receiving a “Hello” message from  $u$ , node  $v$  responds with an *Ack* message. (Recall that we have assumed that  $v$  can compute the power required to respond.) Upon receiving the *Ack* from  $v$ , node  $u$  adds  $v$  to its set  $N_u$  of neighbors and adds  $v$ 's direction  $\text{dir}_u(v)$  (measured as an angle relative to some fixed angle) to its set  $D_u$  of directions. (Recall that we have assumed that  $u$  can compute this angle.) The test  $\text{gap-}\alpha(D_u)$  tests if there is a gap greater than  $\alpha$  in the angles in  $D_u$ .

Let  $N_\alpha(u)$  be the final set of discovered neighbors computed by node  $u$  at the end of running  $\text{CBTC}(\alpha)$ ; let  $p_{u,\alpha}$  be the corresponding final power. Let  $N_\alpha = \{(u, v) \in V \times V : v \in N_\alpha(u)\}$ . Note that the  $N_\alpha$  relation is not symmetric. As the following example shows, it is possible that  $(v, u) \in N_\alpha$  but  $(u, v) \notin N_\alpha$ .

CBTC( $\alpha$ )

$N_u \leftarrow \emptyset$ ; //the set of discovered neighbors of  $u$   
 $D_u \leftarrow \emptyset$ ; //the directions from which the Acks have come  
 $p_u \leftarrow p_0$ ;

**while**  $p_u < p_{max}$  and  $gap-\alpha(D_u)$  **do**  
 $p_u \leftarrow Increase(p_u)$ ;  
 $bcast(u, p_u, ("Hello", p_u))$  and gather Acks;  
 $N_u \leftarrow N_u \cup \{v : v \text{ discovered}\}$ ;  
 $D_u \leftarrow D_u \cup \{dir_u(v) : v \text{ discovered}\}$

Figure 1: The basic cone-based algorithm running at each node  $u$ .

**Example 2.1** Suppose that  $V = \{u_0, u_1, u_2, u_3, v\}$ . (See Figure 2.) Further suppose that  $d(u_0, v) = R$ . Choose  $\epsilon$  with  $0 < \epsilon < \pi/12$  and place  $u_1, u_2, u_3$  so that (1)  $\angle vu_0u_1 = \angle vu_0u_2 = \pi/3 + \epsilon = \alpha/2$ , (2)  $\angle u_1vu_0 = \angle u_2vu_0 = \pi/3 - \epsilon$  (so that  $\angle vu_1u_0 = \angle vu_2u_0 = \pi/3$ ), (3)  $\angle vu_0u_3 = \pi$  (so that  $\angle u_1u_0u_3 = \angle u_2u_0u_3 = 2\pi/3 - \epsilon$ ) and (4)  $d(u_0, u_3) = R/2$ . Note that, given  $\epsilon$  and the positions of  $u_0$  and  $v$ , the positions of  $u_1, u_2$ , and  $u_3$  are determined. Since  $\angle u_1u_0v > \angle u_0u_1v > \angle u_1vu_0$ , it follows that  $d(u_1, v) > d(u_0, v) = R > d(u_0, u_1)$ ; similarly  $d(u_2, v) > R > d(u_0, u_2)$ . (Here and elsewhere we use the fact that, in a triangle, larger sides are opposite larger angles.) It easily follows that  $N_\alpha(u_0) = \{u_1, u_2, u_3\}$  while  $N_\alpha(v) = \{u_0\}$ , as long as  $2\pi/3 < \alpha \leq 5\pi/6$ . Thus,  $(v, u_0) \in N_\alpha$ , but  $(u_0, v) \notin N_\alpha$ .

Figure 2:  $N_\alpha$  may not be symmetric.

Let  $G_\alpha = (V, E_\alpha)$ , where  $V$  consists of all nodes in the network and  $E_\alpha$  is the symmetric closure of  $N_\alpha$ ; that is,  $(u, v) \in E_\alpha$  iff either  $(u, v) \in N_\alpha$  or  $(v, u) \in N_\alpha$ . We now prove the two main results of this paper: (1) if  $\alpha \leq 5\pi/6$ , then  $G_\alpha$  preserves the connectivity of  $G_R$  and (2) if  $\alpha > 5\pi/6$ , then  $G_\alpha$  may not preserve the connectivity of  $G_R$ . Note that Example 2.1 shows the need for taking the symmetric closure in computing  $G_\alpha$ . Although  $(u_0, v) \in G_R$ , there would be no path from  $u_0$  to  $v$  if we considered just the edges determined by  $N_\alpha$ , without taking the symmetric closure. (The fact that  $\alpha > 2\pi/3$  in this example is necessary. As we shall see in Section 3.2, taking the symmetric closure is not necessary if  $\alpha \leq 2\pi/3$ .) As we have already observed, each node  $u$  knows the power required to reach all nodes  $v$  such that  $(u, v) \in E_\alpha$ : it is just the max of  $p_{u,\alpha}$  and the power required by  $u$  to reach each of the nodes  $v$  from which it received a ‘‘Hello’’ message. (As we said earlier, if  $u$  receives a ‘‘Hello’’ from  $v$ , since it includes the power used to transmit it,  $u$  can determine the power required for  $u$  to reach  $v$ .)

**Theorem 2.1** *If  $\alpha \leq 5\pi/6$ , then  $G_\alpha$  preserves the connectivity of  $G_R$ ;  $u$  and  $v$  are connected in  $G_\alpha$  iff they are connected in  $G_R$ .*

**Proof:** Since  $G_\alpha$  is a subgraph of  $G_R$ , it is clear that if  $u$  and  $v$  are connected in  $G_\alpha$ , they must be connected in  $G_R$ . To prove the converse, we start with the following key lemma.

**Lemma 2.2** *If  $\alpha \leq 5\pi/6$ , and  $u$  and  $v$  are nodes in  $V$  such that  $(u, v) \in E_R$  (that is,  $(u, v)$  is an edge in the graph  $G_R$ , so that  $d(u, v) \leq R$ ), then either  $(u, v) \in E_\alpha$  or there exist  $u', v' \in V$  such that (a)  $d(u', v') < d(u, v)$ , (b) either  $u' = u$  or  $(u, u') \in E_\alpha$ , and (c) either  $v' = v$  or  $(v, v') \in E_\alpha$ .*

**Proof:** A few definitions will be helpful in this and the following proof. Given two nodes  $u'$  and  $v'$ ,

- Let  $\text{cone}(u', \alpha, v')$  be the cone of degree  $\alpha$  which is bisected by the line  $\overline{u'v'}$ , as in Figure 3;
- Let  $\text{circ}(u, r)$  be the circle centered at  $u$  with radius  $r$ ;
- Let  $\text{rad}_{u,\alpha}^-$  be the distance  $d(u, v)$  of the neighbor  $v$  farthest from  $u$  in  $N_\alpha(u)$ ; that is,  $p(\text{rad}_{u,\alpha}^-) = p_{u,\alpha}$ ;
- Let  $\text{rad}_{u,\alpha}$  be the distance  $d(u, v)$  of the neighbor  $v$  farthest from  $u$  in  $E_\alpha$ .

If  $(u, v) \in E_\alpha$ , we are done. Otherwise, it must be the case that  $d(u, v) > \max(\text{rad}_{u,\alpha}^-, \text{rad}_{v,\alpha}^-)$ . Thus, both  $u$  and  $v$  terminate CBTC( $\alpha$ ) with no  $\alpha$ -gap. It follows that  $\text{cone}(u, \alpha, v) \cap N_\alpha(u) \neq \emptyset$  and  $\text{cone}(v, \alpha, u) \cap N_\alpha(v) \neq \emptyset$ . Choose  $z \in \text{cone}(v, \alpha, u) \cap N_\alpha(v)$  such that  $\angle zvu$  is minimal. (See Figure 4.) Suppose without loss of generality that  $z$  is in the

Figure 3:  $\text{cone}(u', \alpha, v')$

halfplane above  $\overline{uv}$ . If  $z$  is actually in  $\text{cone}(v, 2\pi/3, u)$ , since  $d(v, z) \leq \text{rad}_{v, \alpha}^- < d(u, v)$ , it follows that  $d(z, u) < d(u, v)$ . For otherwise, the side  $zu$  would be at least as long as any other side in the triangle  $vzu$ , so that  $\angle zvu$  would have to be at least as large as any other angle in the triangle. But since  $\angle zvu \leq \pi/3$ , this is impossible. Thus, taking  $u' = u$  and  $v' = z$ , the lemma holds in this case. So we can assume without loss of generality that  $z \notin \text{cone}(v, 2\pi/3, u)$  (and, thus, that  $\text{cone}(v, 2\pi/3, u) \cap N_\alpha(v) = \emptyset$ ). Let  $y$  be the first node in  $N_\alpha(v)$  that a ray that starts at  $vz$  would hit as it sweeps past  $vu$  going counterclockwise. By construction,  $y$  is in the half-plane below  $\overline{uv}$  and  $\angle zvy \leq \alpha$ .

Similar considerations show that, without loss of generality, we can assume that  $\text{cone}(u, 2\pi/3, v) \cap N_\alpha(u) = \emptyset$ , and that there exist two points  $w, x \in N_\alpha(u)$  such that (a)  $w$  is in the halfplane above  $\overline{uv}$ , (b)  $x$  is in the halfplane below  $\overline{uv}$ , (c) at least one of  $w$  and  $x$  is in  $\text{cone}(u, \alpha, v)$ , and (d)  $\angle wux \leq \alpha$ . See Figure 4.

If  $d(w, v) < d(u, v)$ , then the lemma holds with  $u' = w$  and  $v' = v$ , so we can assume that  $d(w, v) \geq d(u, v)$ . Similarly, we can assume without loss of generality that  $d(z, u) \geq d$ . We now prove that  $d(w, z)$  and  $d(x, y)$  cannot both be greater than or equal to  $d$ . This will complete the proof since, for example, if  $d(w, z) < d$ , then we can take  $u' = w$  and  $v' = z$  in the lemma.

Suppose, by way of contradiction, that  $d(w, z) \geq d$  and  $d(x, y) \geq d$ . Let  $t$  be the intersection point of  $\text{circ}(z, d)$  and  $\text{circ}(v, d)$  that is closest to  $u$ . Recall that at least one of  $w$  and  $x$  is in  $\text{cone}(u, \alpha, v)$ . As we show in Appendix A, since node  $w$  must be outside (or on) both circles  $\text{circ}(z, d)$  and  $\text{circ}(v, d)$ , we have  $\angle wuv \geq \angle tuv$  (see the closeup on the far right side of Figure 4).

Since  $d(t, z) = d(t, v) = d(u, v) = d$ , and  $d(z, v) < d$ , it follows that  $\angle zvt > \pi/3$ . Thus,

$$\begin{aligned} \angle tvu &= \angle zvu - \angle zvt < \angle zvu - \pi/3 \text{ and} \\ \angle tvu &= \pi - 2 \times \angle tuv, \end{aligned}$$

Figure 4: Illustration for the proof of Lemma 2.2.

and so

$$\begin{aligned} \angle zvu - \pi/3 &> \pi - 2 \times \angle tuv \text{ and,} \\ \angle tuv &> 2\pi/3 - \angle zvu/2. \end{aligned}$$

Since  $\angle wuv \geq \angle tuv$ , we have that

$$\angle wuv > 2\pi/3 - \angle zvu/2. \quad (1)$$

By definition of  $z$ ,  $\angle zvu \leq \alpha/2 \leq 5\pi/12$ , so  $\angle wuv > 2\pi/3 - 5\pi/24 = 11\pi/24 > \alpha/2$ . Thus, it must be the case that  $w \notin \text{cone}(u, \alpha, v)$ , so  $x \in \text{cone}(u, \alpha, v)$ .

Arguments identical to those used to derive (1) (replacing the role of  $w$  and  $z$  by  $x$  and  $y$ , respectively) can be used to show that

$$\angle yvu > 2\pi/3 - \angle xuv/2. \quad (2)$$

From (1) and (2), we have

$$\begin{aligned} &\angle wuv + \angle xuv \\ &> (2\pi/3 - \angle zvu/2) + (4\pi/3 - 2 \times \angle yvu) \\ &= 2\pi - \angle zvu/2 - 2 \times \angle yvu. \end{aligned}$$

Since  $\angle wuv + \angle xuv \leq \alpha \leq 5\pi/6$ , we have that  $5\pi/6 > 2\pi - \angle zvu/2 - 2 \times \angle yvu$ . Thus,

$$\angle zvu/2 + 2 \times \angle yvu = ((\angle zvu + \angle yvu) + 3 \times \angle yvu)/2 > 7\pi/6.$$

Since  $\angle zvu + \angle yvu \leq \alpha \leq 5\pi/6$ , it easily follows that  $\angle yvu > \pi/2$ . As we showed earlier,  $\angle zvu \geq \angle zvt > \pi/3$ . Therefore,  $\angle zvu + \angle yvu > 5\pi/6$ . This is a contradiction. ■

The proof of Theorem 2.1 now follows easily. Order the edges in  $E_R$  by length. We proceed by induction on the the rank of the edge in the ordering to show that if  $(u, v) \in E_R$ , then there is a path from  $u$  to  $v$  in  $G_\alpha$ . For the base case, if  $(u, v)$  is the shortest edge in  $E_R$ , then it is immediate from Lemma 2.2 that  $(u, v) \in E_\alpha$ . For note that, by construction, if  $(u, v) \in E_R$  and  $d(u', v') < d(u, v)$ , then  $(u', v') \in E_R$  and is a shorter edge than  $(u, v)$ . For the inductive step, suppose that  $(u, v)$  is the  $k$ th shortest edge in  $E_R$  and, by way of contradiction, that  $(u, v)$  is not in  $E_\alpha$ . By Lemma 2.2, there exist  $u', v' \in V$  such that (a)  $d(u', v') < d(u, v)$ , (b) either  $u = u'$  or  $d(u, u') \in E_\alpha$ , and (c) either  $v = v'$  or  $d(v, v') \in E_\alpha$ . As we observed, it follows that  $(u', v') \in E_R$ . Since  $d(u', v') < d(u, v)$ , by the inductive hypothesis, it follows that there is an path from  $u'$  to  $v'$  in  $G_\alpha$ . Since  $E_\alpha$  is symmetric, it is immediate that there is also a path from  $u$  to  $v$  in  $G_\alpha$ . It immediately follows that if  $u$  and  $v$  are connected in  $G_R$ , then there is a path from  $u$  to  $v$  in  $G_\alpha$ . ■

The proof of Theorem 2.1 gives some extra information, which we cull out as a separate corollary:

**Corollary 2.3** *If  $\alpha \leq 5\pi/6$ , and  $u$  and  $v$  are nodes in  $V$  such that  $(u, v) \in E_R$ , then either  $(u, v) \in E_\alpha$  or there exists a path  $u_0 \dots u_k$  such that  $u_0 = u$ ,  $u_k = v$ ,  $(u_i, u_{i+1}) \in E_\alpha$ , and  $d(u_i, u_{i+1}) < d(u, v)$ , for  $i = 0, \dots, k - 1$ .*

Next we prove that degree  $5\pi/6$  is a tight upper bound; if  $\alpha > 5\pi/6$ , then  $\text{CBTC}(\alpha)$  does not necessarily preserve connectivity.

**Theorem 2.4** *If  $\alpha > 5\pi/6$ , then  $\text{CBTC}(\alpha)$  does not necessarily preserve connectivity.*

**Proof:** Suppose  $\alpha = 5\pi/6 + \epsilon$  for some  $\epsilon > 0$ . We construct a graph  $G_R = (V, E_R)$  such that  $\text{CBTC}(\alpha)$  does not preserve the connectivity of this graph.  $V$  has eight nodes:  $u_0, u_1, u_2, u_3, v_0, v_1, v_2, v_3$ . (See Figure 5.) We call  $u_0, u_1, u_2, u_3$  the  $u$ -cluster, and  $v_0, v_1, v_2, v_3$  the  $v$ -cluster. The construction has the property that  $d(u_0, v_0) = R$  and for  $i, j = 0, 1, 2, 3$ , we have  $d(u_0, u_i) < R$ ,  $d(v_0, v_i) < R$ , and  $d(u_i, v_j) > R$  if  $i + j \geq 1$ . That is, the only edge between the  $u$ -cluster and the  $v$ -cluster in  $G_R$  is  $(u_0, v_0)$ . However, in  $G_\alpha$ , the  $(u_0, v_0)$  edge disappears, so that the  $u$ -cluster and the  $v$ -cluster are disconnected.

In Figure 5,  $s$  and  $s'$  are the intersection points of the circles of radius  $R$  centered at  $u_0$  and  $v_0$ , respectively. Node  $u_1$  is chosen so that  $\angle u_1 u_0 v_0 = \pi/2$ . Similarly,  $v_1$  is chosen so that  $\angle v_1 v_0 u_0 = \pi/2$  and  $u_1$  and  $v_1$  are on opposite sides of the line  $\overline{u_0 v_0}$ . Because of the right angle, it is clear that, whatever  $d(u_0, u_1)$  is, we must have  $d(v_0, u_1) > d(v_0, u_0) = R$ ; similarly,  $d(u_0, v_1) > R$  whatever  $d(v_0, v_1)$  is. Next, choose  $u_2$  so that  $\angle u_1 u_0 u_2 = \min(\alpha, \pi)$  and  $u_0 u_2$  comes after  $u_0 u_1$  as a ray sweeps around counterclockwise from  $u_0 v_0$ . It is easy to see that  $d(v_0, u_2) > R$ , whatever  $d(u_0, u_2)$  is, since  $\angle v_0 u_0 u_2 \geq \pi/2$ . For definiteness, choose  $u_2$  so that  $d(u_0, u_2) = R/2$ . Node  $v_2$  is chosen similarly. The key step in the construction is the choice of  $u_3$  and  $v_3$ . Note that  $\angle s' u_0 u_1 = 5\pi/6$ . Let  $u_3$  be a point on the line through  $s'$  parallel to  $\overline{u_0 v_0}$  slightly to the left of  $s'$  such that  $\angle u_3 u_0 u_1 < \alpha$ .

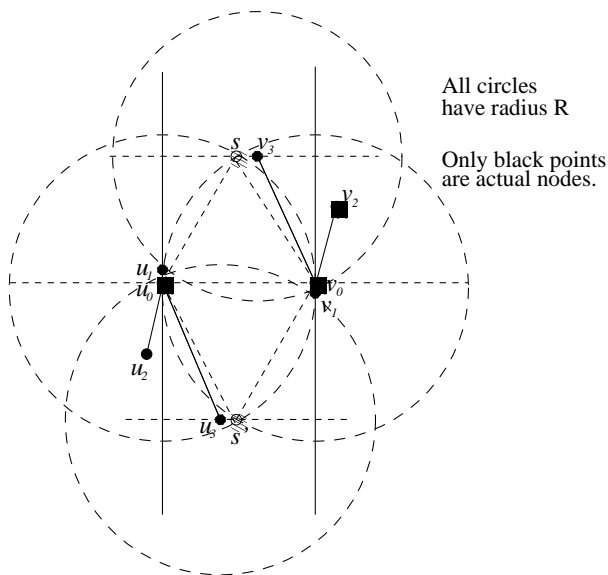

Figure 5: A disconnected graph if  $\alpha = 5\pi/6 + \epsilon$ .

Since  $\alpha = 5\pi/6 + \epsilon$ , it is possible to find such a node  $u_3$ . Since  $d(u_0, s') = d(v_0, s') = R$  by construction, it follows that  $d(u_0, u_3) < R$  and  $d(v_0, u_3) > R$ . It is clearly possible to choose  $d(v_0, v_1)$  sufficiently small so that  $d(u_3, v_1) > R$ . The choice of  $v_3$  is similar.

It is now easy to check that when  $u_0$  runs  $\text{CBTC}(\alpha)$ , it will terminate with  $p_{u_0, \alpha} = \max(d(u_0, u_3), R/2) < R$ ; similarly for  $v_0$ . Thus, this construction has all the required properties. ■

### 3 Optimizations

In this section, we describe three optimizations to the basic algorithm. We prove that these optimizations allow some of the edges to be removed while still preserving connectivity.

#### 3.1 The shrink-back operation

In the basic  $\text{CBTC}(\alpha)$  algorithm,  $u$  is said to be a *boundary node* if, at the end of the algorithm,  $u$  still has an  $\alpha$ -gap. Note that this means that, at the end of the algorithm, a boundary node broadcasts with maximum power. An optimization would be to add a shrinking phase at the end of the growing phase to allow each boundary node to broadcast with less power, if it can do so without reducing its cone coverage. To make this precise, given a set  $dir$  of directions (angles) and an angle  $\alpha$ , define  $cover_\alpha(dir) = \{\theta : \text{for some}$

$\theta' \in \text{dir}, |\theta - \theta'| \bmod 2\pi \leq \alpha/2\}$ . We modify CBTC( $\alpha$ ) so that, at each iteration, a node in  $N_u$  is tagged with the power used the first time it was discovered. Suppose that the power levels used by node  $u$  during the algorithm were  $p_1, \dots, p_k$ . If  $u$  is a boundary node,  $p_k$  is the maximum power  $p_{max}$ . A boundary node successively removes nodes tagged with power  $p_k$ , then  $p_{k-1}$ , and so on, as long as their removal does not change the coverage. That is, let  $\text{dir}_i, i = 1, \dots, k$ , be the set of directions found with all power levels  $p_i$  or less, then the minimum  $i$  such that  $\text{cover}_\alpha(\text{dir}_i) = \text{cover}_\alpha(\text{dir}_k)$  is found. Let  $N_\alpha^s(u)$  consist of all the nodes in  $N_\alpha(u)$  tagged with power  $p_i$  or less. Let  $N_\alpha^s = \{(u, v) : v \in N_\alpha^s(u)\}$ , and let  $E_\alpha^s$  be the symmetric closure of  $N_\alpha^s$ . Finally, let  $G_\alpha^s = (V, E_\alpha^s)$ .

**Theorem 3.1** *If  $\alpha \leq 5\pi/6$ , then  $G_\alpha^s$  preserves the connectivity of  $G_R$ .*

**Proof:** It is easy to check that the proof of Theorem 2.1 depended only on the cone coverage of each node, so it goes through without change. In more detail, given any two nodes  $u$  and  $v$  in  $G_\alpha^s$ , if  $d(u, v) = d \leq R$  and  $(u, v) \notin E_\alpha^s$ , then either both  $u$  and  $v$  did not use power sufficient to reach distance  $d$  in the basic CBTC algorithm or one or both of them used enough power to reach distance  $d$  but then shrank back. In either case, nodes  $u$  and  $v$  must still have neighbors in  $N_\alpha^s(u)$  and  $N_\alpha^s(v)$  fully covering the cones  $\text{cone}(u, \alpha, v)$  and  $\text{cone}(v, \alpha, u)$ , respectively, since any shrink-back operation can only remove those neighbors that provide redundant cone coverage. Thus, the proof of Lemma 2.2 goes through with no change. The remainder of the argument follows exactly the same lines as that of the proof of Theorem 2.1. ■

Note that this argument actually shows that we can remove any nodes from  $N_u$  that do not contribute to the cone coverage. However, our interest here lies in minimizing the power needed for broadcast, not in minimizing the number of nodes in  $N_u$ . There may be some applications where it helps to reduce the degree of a node; in this case, removing further nodes may be a useful optimization.

### 3.2 Asymmetric edge removal

As shown by Example 2.1, in order to preserve connectivity, it is necessary to add an edge  $(u, v)$  to  $E_\alpha$  if  $(v, u) \in N_\alpha$ , even if  $(u, v) \notin N_\alpha$ . In Example 2.1,  $\alpha > 2\pi/3$ . This is not an accident. As we now show, if  $\alpha \leq 2\pi/3$ , not only don't we have to add an edge  $(u, v)$  if  $(v, u) \in N_\alpha$ , we can *remove* an edge  $(v, u)$  if  $(v, u) \in N_\alpha$  but  $(u, v) \notin N_\alpha$ . Let  $E_\alpha^- = \{(u, v) : (u, v) \in N_\alpha \text{ and } (v, u) \in N_\alpha\}$ . Thus, while  $E_\alpha$  is the smallest symmetric set containing  $N_\alpha$ ,  $E_\alpha^-$  is the largest symmetric set contained in  $N_\alpha$ . Let  $G_\alpha^- = (V, E_\alpha^-)$ .

**Theorem 3.2** *If  $\alpha \leq 2\pi/3$ , then  $G_\alpha^-$  preserves the connectivity of  $G_R$ .*

**Proof:** We start by proving the following lemma, which strengthens Corollary 2.3.

**Lemma 3.3** *If  $\alpha \leq 2\pi/3$ , and  $u$  and  $v$  are nodes in  $V$  such that  $(u, v) \in E_R$ , then either  $(u, v) \in N_\alpha$  or there exists a path  $u_0 \dots u_k$  such that  $u_0 = u$ ,  $u_k = v$ ,  $(u_i, u_{i+1}) \in N_\alpha$ , and  $d(u_i, u_{i+1}) < d(u, v)$ , for  $i = 0, \dots, k - 1$ .*

**Proof:** Order the edges in  $E_R$  by length. We proceed by strong induction on the rank of an edge in the ordering. Given an edge  $(u, v) \in E_R$  of rank  $k$  in the ordering, if  $(u, v) \in N_\alpha$ , we are done. If not, as argued in the proof of Lemma 2.2, there must be a node  $w \in \text{cone}(u, \alpha, v) \cap N_\alpha(u)$ . Since  $\alpha \leq 2\pi/3$ , the argument in the proof of Lemma 2.2 also shows that  $d(w, v) < d(u, v)$ . Thus,  $(w, v) \in E_R$  and has lower rank in the ordering of edges. Applying the induction hypothesis, the lemma holds for  $(u, v)$ . This completes the proof. ■

Lemma 3.3 shows that if  $(u, v) \in E_R$ , then there is a path consisting of edges in  $N_\alpha$  from  $u$  to  $v$ . This is not good enough for our purposes; we need a path consisting of edges in  $E_\alpha^-$ . The next lemma shows that this is also possible.

**Lemma 3.4** *If  $\alpha \leq 2\pi/3$ , and  $u$  and  $v$  are nodes in  $V$  such that  $(u, v) \in N_\alpha$ , then there exists a path  $u_0 \dots u_k$  such that  $u_0 = u$ ,  $u_k = v$ ,  $(u_i, u_{i+1}) \in E_\alpha^-$ , for  $i = 0, \dots, k - 1$ .*

**Proof:** Order the edges in  $N_\alpha$  by length. We proceed by strong induction on the rank of an edge in the ordering. Given an edge  $(u, v) \in N_\alpha$  of rank  $k$  in the ordering, if  $(u, v) \in E_\alpha^-$ , we are done. If not, we must have  $(v, u) \notin N_\alpha$ . Since  $(v, u) \in E_R$ , by Lemma 3.3, there is a path from  $v$  to  $u$  consisting of edges in  $N_\alpha$  all of which have length smaller than  $d(v, u)$ . If any of these edges is in  $N_\alpha - E_\alpha^-$ , we can apply the inductive hypothesis to replace the edge by a path consisting only of edges in  $E_\alpha^-$ . By the symmetry of  $E_\alpha^-$ , such a path from  $v$  to  $u$  implies a path from  $u$  to  $v$ . This completes the inductive step. ■

The proof of Theorem 3.2 is now immediate from Lemmas 3.3 and 3.4. ■

To implement asymmetric edge removal, the basic CBTC needs to be enhanced slightly. After finishing  $\text{CBTC}(\alpha)$ , a node  $u$  must send a message to each node  $v$  to which it sent an *Ack* message that is not in  $N_\alpha(u)$ , telling  $v$  to remove  $u$  from  $N_\alpha(v)$  when constructing  $E_\alpha^-$ . It is easy to see that the shrink-back optimization discussed in Section 3.1 can be applied together with the removal of these asymmetric edges.

There is a tradeoff between using  $\text{CBTC}(5\pi/6)$  and using  $\text{CBTC}(2\pi/3)$  with asymmetric edge removal. In general,  $p_{u,5\pi/6}$  (i.e.,  $p(\text{rad}_{u,5\pi/6}^-)$ ) will be smaller than  $p_{u,2\pi/3}$ . However, the power  $p(\text{rad}_{u,5\pi/6})$  with which  $u$  needs to transmit may be greater than  $p_{u,5\pi/6}$  since  $u$  may need to reach nodes  $v$  such that  $u \in N_{5\pi/6}(v)$  but  $v \notin N_{5\pi/6}(u)$ . In contrast, if  $\alpha = 2\pi/3$ , then asymmetric edge removal allows  $u$  to still use  $p_{u,2\pi/3}$  and may allow  $v$  to use power less than  $p_{v,2\pi/3}$ . Our experimental results confirm this. See Section 5.

### 3.3 Pairwise edge removal

The final optimization aims at further reducing the transmission power of each node. In addition to the directional information, this optimization requires two other pieces of information. First, each node  $u$  is assigned a unique integer ID denoted  $ID_u$ , and that  $ID_u$  is included in all of  $u$ 's messages. Second, although a node  $u$  does not need to know its exact distance from its neighbors, given any pair of neighbors  $v$  and  $w$ , node  $u$  needs to know which of them is closer. This can be achieved as follows. Recall that a node grows its radius in discrete steps. It includes its transmission power level in each of the "Hello" messages. Each discovered neighbor node also includes its transmission power level in the *Ack*. When  $u$  receives messages from nodes  $v_1$  and  $v_2$ , it can deduce which of  $v_1$  and  $v_2$  is closer based on the transmission and reception powers of the messages.

Even after the shrink-back operation and possibly asymmetric edge removal, there are many edges that can be removed while still preserving connectivity. For example, if three edges form a triangle, we can clearly remove any one of them while still maintaining connectivity. In this section, we improve on this result by showing that if there is an edge from  $u$  to  $v_1$  and from  $u$  to  $v_2$ , then we can remove the longer edge even if there is no edge from  $v_1$  to  $v_2$ , as long as  $d(v_1, v_2) < \max(d(u, v_1), d(u, v_2))$ . Note that a condition sufficient to guarantee that  $d(v_1, v_2) < \max(d(u, v_1), d(u, v_2))$  is that  $\angle v_1 u v_2 < \pi/3$  (since the longest edge will be opposite the largest angle).

To make this precise, we use the notion of an edge ID. Each edge  $(u, v)$  is assigned an edge ID  $eid(u, v) = (i_1, i_2, i_3)$ , where  $i_1 = d(u, v)$ ,  $i_2 = \max(ID_u, ID_v)$ , and  $i_3 = \min(ID_u, ID_v)$ . Edge IDs are compared lexicographically, so that  $(i, j, k) < (i', j', k')$  iff either (a)  $i < i'$ , (b)  $i = i'$  and  $j < j'$ , or (c)  $i = i'$ ,  $j = j'$ , and  $k < k'$ .

**Definition 3.5** If  $v$  and  $w$  are neighbors of  $u$ ,  $\angle v u w < \pi/3$ , and  $eid(u, v) > eid(u, w)$ , then  $(u, v)$  is a *redundant edge*.

As the name suggests, redundant edges are redundant, in that it is possible to remove them while still preserving connectivity. The following theorem proves this.

**Theorem 3.6** For  $\alpha \leq 5\pi/6$ , all redundant edges can be removed while still preserving connectivity.

**Proof:** Let  $E_\alpha^{nr}$  consist of all the non-redundant edges in  $E_\alpha$ . We show that if  $(u, v) \in E_\alpha - E_\alpha^{nr}$ , then there is a path from  $u$  to  $v$  consisting only of edges in  $E_\alpha^{nr}$ . Clearly, this suffices to prove the theorem.

Let  $e_1, e_2, \dots, e_m$  be a listing of the redundant edges (i.e, those in  $E_\alpha - E_\alpha^{nr}$ ) in increasing lexicographic order of edge ID. We prove, by induction on  $k$ , that for every redundant edge  $e_k = (u_k, v_k)$  there is a path from  $u_k$  to  $v_k$  consisting of edges in  $E_\alpha^{nr}$ . For the base case, consider  $e_1 = (u_1, v_1)$ . By definition, there must exist an edge  $(u_1, w_1)$  such that  $\angle v_1 u_1 w_1 < \pi/3$  and  $eid(u_1, v_1) > eid(u_1, w_1)$ . Since  $e_1$  is the redundant edge

with the smallest edge ID,  $(u_1, w_1)$  cannot be a redundant edge. Since  $\angle v_1 u_1 w_1 < \pi/3$ , it follows that  $d(w_1, v_1) < d(u_1, v_1)$ . If  $(w_1, v_1) \in E_\alpha$ , then  $(w_1, v_1) \in E_\alpha^{nr}$  (since  $(u_1, v_1)$  is the shortest redundant edge) and  $(u_1, w_1), (w_1, v_1)$  is the desired path of non-redundant edges. On the other hand, if  $(w_1, v_1) \notin E_\alpha$  then, since  $d(w_1, v_1) < d(u_1, v_1) \leq R$  and  $\alpha \leq 5\pi/6$ , by Corollary 2.3, there exists a path from  $w_1$  to  $v_1$  consisting of edges in  $E_\alpha$  all shorter than  $d(w_1, v_1)$ . Since none of these edges can be redundant edge, this gives us the desired path.

For the inductive step, suppose that for every  $e_j = (u_j, v_j)$ ,  $1 \leq j \leq i - 1$ , we have found a path  $H'_j$  between  $u_j$  and  $v_j$ , which contains no redundant edges. Now consider  $e_i = (u_i, v_i)$ . Again, by definition, there exists another edge  $(u_i, w_i)$  with  $eid(u_i, v_i) > eid(u_i, w_i)$  and  $\angle v_i u_i w_i < \pi/3$ . If  $(u_i, w_i)$  is a redundant edge, it must be one of  $e_j$ 's, where  $j \leq i - 1$ . Moreover, if the path  $H_i$  (from Corollary 2.3) between  $v_i$  and  $w_i$  contains a redundant edge  $e_j$ , we must have  $|e_j| < |e_i|$  and so  $j \leq i - 1$ . By connecting  $(u_i, w_i)$  with  $H_i$  and replacing every redundant edge  $e_j$  on the path with  $H'_j$ , we obtain a path  $H'_i$  between  $u_i$  and  $v_i$  that contains no redundant edges. This completes the proof. ■

Although Theorem 3.6 shows that all redundant edges can be removed, this doesn't mean that all of them should necessarily be removed. For example, if we remove some edges, the paths between nodes become longer, in general. Since some overhead is added for each link a message traverses, having fewer edges can affect network throughput. In addition, if routes are known and many messages are being sent using point-to-point communication between different senders and receivers, having fewer edges is more likely to cause congestion. Since we would like to reduce the transmission power of each node, we remove only redundant edges with length greater than the longest non-redundant edges. We call this optimization the *pairwise edge removal* optimization.

## 4 Dealing with reconfiguration, asynchrony, and failures

In a multi-hop wireless network, nodes can be mobile. Even if nodes do not move, nodes may die if they run out of energy. In addition, new nodes may be added to the network. We need a mechanism to detect such changes in the network. This is done by the Neighbor Discovery Protocol (NDP). A NDP is usually a simple beaconing protocol for each node to tell its neighbor that it is still alive. The beacon includes the sending node's ID and the transmission power of the beacon. A neighbor is considered failed if a pre-defined number of beacons are not received for a certain time interval  $\tau$ . A node  $v$  is considered a new neighbor of  $u$  if a beacon is received from  $v$  and no beacon was received from  $v$  during the previous  $\tau$  interval.

The question is what power a node should use for beaconing. Certainly a node  $u$  should broadcast with sufficient power to reach all of its neighbors in  $E_\alpha$  (or  $E_\alpha^-$ , if  $\alpha \leq 2\pi/3$ ). As we will show, if  $u$  uses a beacon with power  $p(rad_{u,\alpha})$  (recall that  $p(rad_{u,\alpha})$

is the power that  $u$  must use to reach all its neighbors in  $E_\alpha$ ), then this is sufficient for reconfiguration to work with the basic cone-based algorithm (possibly combined with asymmetric edge removal if  $\alpha \leq 2\pi/3$ , in which case we can use power  $p(\text{rad}_{u,\alpha}^-)$ ).

We define three basic events:

- A  $\text{join}_u(v)$  event happens when node  $u$  detects a beacon from node  $v$  for the first time;
- A  $\text{leave}_u(v)$  event happens when node  $u$  misses some predetermined number of beacons from node  $v$ ;
- An  $\text{aChange}_u(v)$  event happens when  $u$  detects that  $v$ 's angle with respect to  $u$  has changed. (Note this could be due to movement by either  $u$  or  $v$ .)

Our reconfiguration algorithm is very simple. It is convenient to assume that each node is tagged with the power used when it was first discovered, as in the shrink-back operation. (This is not necessary, but it minimizes the number of times that CBTC needs to be rerun.)

- If a  $\text{leave}_u(v)$  event happens, and if there is an  $\alpha$ -gap after dropping  $\text{dir}_u(v)$  from  $D_u$ , node  $u$  reruns CBTC( $\alpha$ ) (as in Figure 1), starting with power  $p(\text{rad}_{u,\alpha}^-)$  (i.e., taking  $p_0 = p(\text{rad}_{u,\alpha}^-)$ ).
- If a  $\text{join}_u(v)$  event happens,  $u$  computes  $\text{dir}_u(v)$  and the power needed to reach  $v$ . As in the shrink-back operation,  $u$  then removes nodes, starting with the farthest neighbor nodes and working back, as long as their removal does not change the coverage.
- If an  $\text{aChange}_u(v)$  event happens, node  $u$  modifies the set  $D_u$  of directions appropriately. If an  $\alpha$ -gap is then detected, then CBTC( $\alpha$ ) is rerun, again starting with power  $p(\text{rad}_{u,\alpha}^-)$ . Otherwise, nodes are removed, as in the shrink-back operation, to see if less power can be used.

In general, there may be more than one change event that is detected at a given time by a node  $u$ . (For example, if  $u$  moves, then there will be in general several  $\text{leave}$ ,  $\text{join}$  and  $\text{aChange}$  events detected by  $u$ .) If more than one change event is detected by  $u$ , we perform the changes suggested above as if the events are observed in some order, as long as there is no need to rerun CBTC. If CBTC needs to be rerun, it deals with all changes simultaneously.

Intuitively, this reconfiguration algorithm preserves connectivity. We need to be a little careful in making this precise, since if the topology changes frequently enough, the reconfiguration algorithm may not ever catch up with the changes, so there may be no point at which the connectivity of the network is actually preserved. Thus, what we want to show is that if the topology ever stabilizes, so that there are no further

changes, then the reconfiguration algorithm eventually results in a graph that preserves the connectivity of the final network, as long as there are periodic beacons. It should be clear that the reconfiguration algorithm guarantees that each cone of degree  $\alpha$  around a node  $u$  is covered (except for boundary nodes), just as the basic algorithm does. Thus, the proof that the reconfiguration algorithm preserves connectivity follows immediately from the proof of Theorem 2.1.

While this reconfiguration algorithm works in combination with the basic algorithm CBTC( $\alpha$ ) and in combination with the asymmetric edge removal optimization, we must be careful in combining it with the other optimizations discussed in Section 3. In particular, we must be very careful about what power a node should use for its beacon. For example, if the shrink-back operation is performed, using the power to reach all the neighbors in  $G_\alpha^s$  does not suffice. For suppose that the network is temporarily partitioned into two subnetworks  $G_1$  and  $G_2$ ; for every pair of nodes  $u_1 \in G_1$  and  $u_2 \in G_2$ , the distance  $d(u_1, u_2) > R$ . Suppose that  $u_1$  is a boundary node in  $G_1$  and  $u_2$  is a boundary node in  $G_2$ , and that, as a result of the shrink-back operation, both  $u_1$  and  $u_2$  use power  $P' < p_{max}$ . Further suppose that later nodes  $u_1$  and  $u_2$  move closer together so that  $d(u_1, u_2) < R$ . If  $P'$  is not sufficient power for  $u_1$  to communicate with  $u_2$ , then they will never be aware of each other's presence, since their beacons will not reach each other, so they will not detect that the network has become reconnected. Thus, network connectivity is *not* preserved.

This problem can be solved by having the boundary nodes broadcast with the power computed by the basic CBTC( $\alpha$ ) algorithm, namely  $p_{max}$  in this case. Similarly, with the pairwise edge removal optimization, it is necessary for  $u$ 's beacon to broadcast with  $p(rad_{u,\alpha})$ , i.e., the power needed to reach all of  $u$ 's neighbors in  $E_\alpha$ , not just the power needed to reach all of  $u$ 's neighbors in  $E_\alpha^{nr}$ . It is easy to see that this choice of beacon power guarantees that the reconfiguration algorithm works.

It is worth noting that a reconfiguration protocol works perfectly well in an asynchronous setting. In particular, the synchronous model with reliable channels that has been assumed up to now can be relaxed to allow asynchrony and both communication and node failures. Now nodes are assumed to communicate asynchronously, messages may get lost or duplicated, and nodes may fail (although we consider only *crash* failures: either a node crashes and stops sending messages, or it follows its algorithm correctly). We assume that messages have unique identifiers and that mechanisms to discard duplicate messages are present. Node failures result in *leave* events, as do lost messages. If node  $u$  gets a message after many messages having been lost, there will be a *join* event corresponding to the earlier *leave* event.

## 5 Experimental Results

How effective is our algorithm and its optimizations as compared to other approaches? Before we answer this question, let us briefly review existing approaches. To our knowl-

edge, among the topology-control algorithms in the literature [23, 8, 9, 20, 22], only Rodoplu and Meng’s algorithm [22] attempts to optimize for energy efficiency while maintaining network connectivity. Following [14], we refer to Rodoplu and Meng’s algorithm as the *MECN* algorithm (for *minimum-energy communication network*) in [14]. The work in [23, 8, 9] tries to maximize network throughput. Their algorithms do not guarantee network connectivity. Ramanathan and Rosales-Hain [20] have considered minimizing the maximum transmission power of all nodes by using centralized MST algorithms. However, their distributed heuristic algorithms do not guarantee network connectivity. Since we are only interested in algorithms that preserve connectivity and are energy efficient, it seems that the only relevant algorithm in the literature is the MECN algorithm. However, since the SMECN algorithm discussed in [14] outperforms MECN, we will compare our algorithm with SMECN only.

We refer to the basic algorithm as CBTC, and to our complete algorithm with all applicable optimizations as OPT-CBTC.<sup>2</sup> Furthermore, we also make the comparison with the no-topology-control case, where each node always uses the maximum transmission power to send a packet (we refer to this approach as MaxPower). In the case of no-topology-control, the reason that we choose maximum power is that it guarantees that there will be no network partitions due to insufficient transmission power.

## 5.1 Simulation Environment

The topology-control algorithms—CBTC, SMECN and MaxPower—are implemented in the ns-2 network simulator [19], using the wireless extension developed at Carnegie Mellon [5]. We generated 20 random networks, each with 200 nodes. Each node has a maximum transmission range of 500 meters and initial energy of 0.5 Joule. The nodes are placed uniformly at random in a rectangular region of 1500 by 1500 meters. There has been some work on realistic topology generation [28, 1]. However, this work has the Internet in mind. Although there have been some papers on realistic topology generation [28, 1], most of them have focused on the Internet setting. Since large multihop wireless networks such as sensor networks are often deployed in a somewhat random fashion (for example, an airplane may drop sensors over some geographical region), we believe that assuming nodes are placed uniformly at random is not an unreasonable assumption.

We assume the two-ray propagation model for terrestrial communications [21]. A transmission between node  $u$  and  $v$  takes power  $p(u, v) = td(u, v)^n$  for some appropriate constant  $t$ , where  $n \geq 2$  is the path-loss exponent of outdoor radio propagation models, and  $d(u, v)$  is the distance between  $u$  and  $v$ . The model has been shown to be close to reality in many environment settings [21]. We assume the power required to receive a transmission at the receiver is constant. This power is referred to as the receiver power and is denoted by  $c$ . The carrier frequency is 914MHz, and the transmission raw bandwidth 2MHz. We assume omni-directional antennas with 0dB gain, and the antenna is placed

---

<sup>2</sup>For brevity, we will omit the parameter  $\alpha$  in our presentation when it is clear from the context.

1.5 meter above a node. The receive threshold is  $-94\text{dBW}$ . The carrier sense threshold is  $-108\text{dBW}$  and the capture threshold is  $10\text{dB}$ . These parameters simulate the  $914\text{MHz}$  Lucent WaveLAN DSSS radio interface.

In order to simulate the effect of power control in the neighbor-discovery process, we made changes to the physical layer of the ns-2 simulation code. In particular, although ns-2 does not support power control, and uses only one power level, we use eight discrete power levels. This seems to be more in keeping with current practice. For example, currently the Aironet PC4800 supports five transmission-power levels. Eight power levels seems sufficient to provide a realistic simulation of the kind of scenarios that arise in practice. In our simulation, power level 8 gives the maximum transmission range of 250 meters. The *Increase* function in Figure 1 moves from one power level to the next higher level. For the “Hello” packet in the CBTC algorithm, the transmission power level is controlled by the algorithm itself. Specifically, as we discussed in Section 4, node  $u$  broadcasts using the final power  $p_u$  (as determined by the *Increase* function in Figure 1). For point-to-point transmissions from a node  $u$ , the minimum power level needed to reach all of  $u$ ’s neighbors is used. We do not use different power levels for different neighbors because there is a delay associated with changing power levels in practice, which some applications may not be able to tolerate.

To simulate interference and collision, we choose the WaveLAN-I [25] CSMA/CA MAC protocol. Topology control does not by itself provide a routing; a routing protocol is needed. We choose AODV [17] in our simulation.

To simulate the network application traffic, we use the following application scenario. We choose 60 connections, i.e. 60 source-destination pairs, at random (with replacement, so that the sources and destinations are not necessarily distinct). For each of these 60 connections in sequence, the source (if it is still alive) sends constant bit rate (CBR) traffic to its destination. The sending rate is 2 packets/sec and the packet size is 512 bytes. This traffic pattern seems to generate sufficient load in the network for our evaluation. We do not expect that the results would be qualitatively different if fewer or more connections were used.

## 5.2 Network Topology Characteristics

Before comparing CBTC with SMECN and MaxPower through detailed network simulation, we first examine the communication graphs that result from using each of these approaches. To achieve this, we use the 20 random networks described in Section 5.1.

Figure 6 illustrates how CBTC and the various optimizations improve network topology using the results from one of these random networks. Figure 6(a) shows a topology graph produced by MaxPower. Figures 6(b) and (c) show the corresponding graphs produced by  $\text{CBTC}(2\pi/3)$  and  $\text{CBTC}(5\pi/6)$  respectively. We can see that both  $\text{CBTC}(2\pi/3)$  and  $\text{CBTC}(5\pi/6)$  allow nodes in the dense areas to automatically reduce their transmission radius. Figures 6(d) and (e) illustrate the graphs after the shrink-back operation

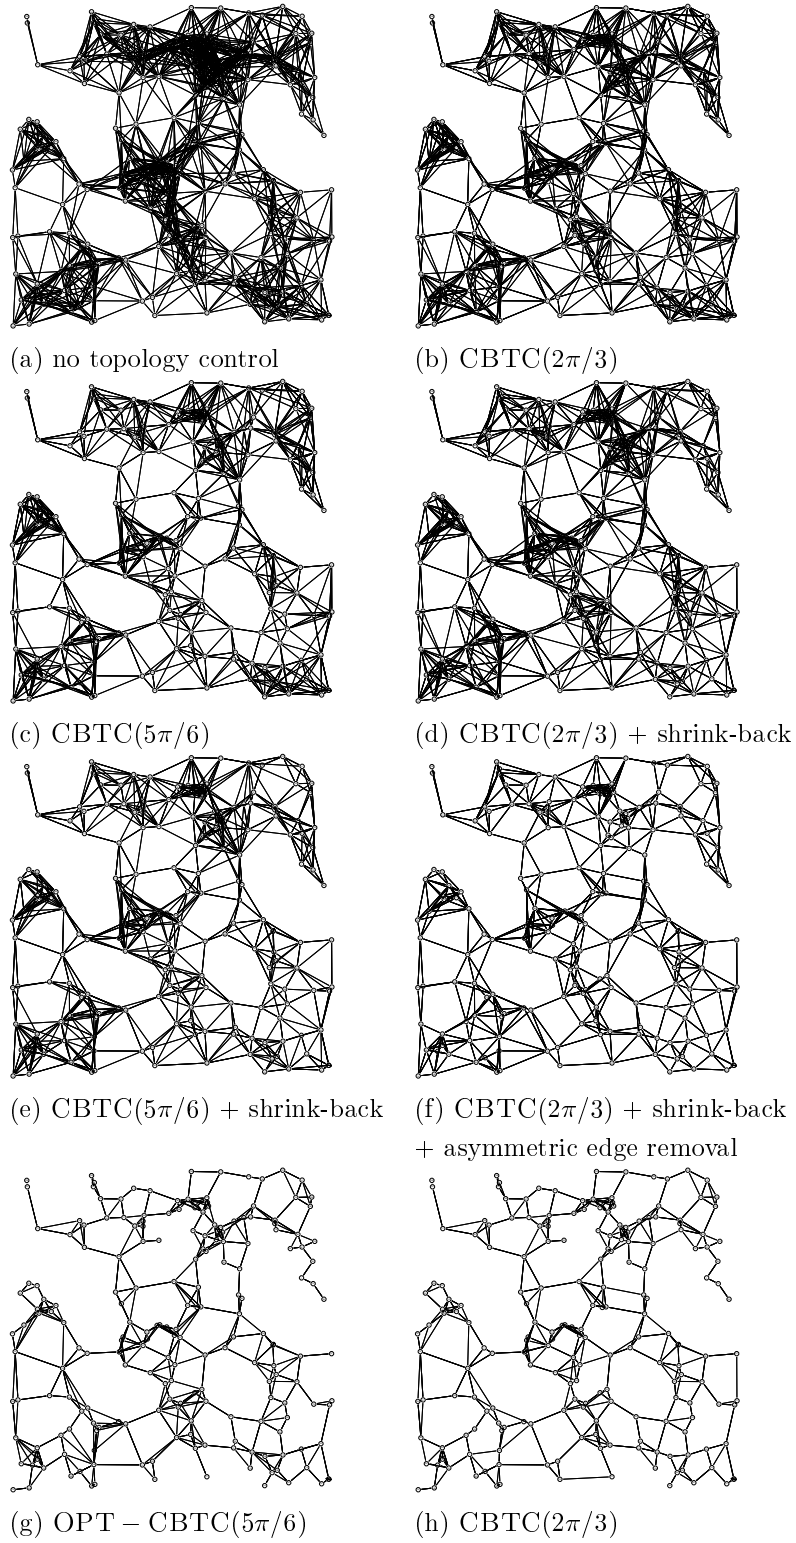

Figure 6: The network graphs after different optimizations.

is performed. Figure 6(f) shows the graph for  $\alpha = 2\pi/3$  as a result of the shrink-back operation and the asymmetric edge removal. Figures 6(g) and (h) show the topology graphs after all applicable optimizations. We can see that the optimizations are very effective in further reducing the transmission radius of nodes.

Table 1 compares the network graphs resulted from cone-based algorithm parameterized by  $\alpha = 2\pi/3$  and  $\alpha = 5\pi/6$  in terms of average node degree and average radius. It also shows the corresponding results for SMECN and MaxPower. The results are averaged over the 20 random networks mentioned earlier. As expected, using a larger value of  $\alpha$  results in a smaller node degree and radius. However, as we discussed in Section 3.2, there is a tradeoff between using CBTC( $2\pi/3$ ) and CBTC( $5\pi/6$ ). Using the basic algorithm,  $rad_{u,5\pi/6} = 205.4 < rad_{u,2\pi/3} = 220.6$ . After applying asymmetric edge removal with  $\alpha = 2\pi/3$ , the resulting radius is 176.6. Hence, asymmetric edge removal can result in significant savings. After applying all applicable optimizations, both  $\alpha = 2\pi/3$  and  $\alpha = 5\pi/6$  end up with very similar results in terms of both average node degree and average radius. However, there are secondary advantages to setting  $\alpha = 5\pi/6$ . In general, CBTC( $5\pi/6$ ) will terminate sooner than CBTC( $2\pi/3$ ) and so expend less power during its execution (since  $p_{u,5\pi/6} < p_{u,2\pi/3}$ ). Thus, if reconfiguration happens frequently, the advantage of using CBCT( $5\pi/6$ ) over CBCT( $2\pi/3$ ) in terms of reduction on power consumption can be significant.

		Average Node Degree	Average radius
Basic	$\alpha = 5\pi/6$	8.8	205.4
	$\alpha = 2\pi/3$	10.9	220.6
with $op_1$	$\alpha = 5\pi/6$	8.3	194.3
	$\alpha = 2\pi/3$	10.1	209.4
with $op_2$	$\alpha = 2\pi/3$	6.9	176.6
with $op_1$ and $op_2$	$\alpha = 2\pi/3$	6.7	171.8
with all optimizations	$\alpha = 5\pi/6$	3.8	110.7
	$\alpha = 2\pi/3$	3.7	113.1
SMECN with $c = 0$	N/A	2.7	115.8
SMECN with $c = 20$	N/A	5.9	148.7
MaxPower	N/A	15.0	250

Table 1: Average degree and radius of the cone-based topology control algorithm with different  $\alpha$  and optimizations ( $op_1$ –shrink-back,  $op_2$ –asymmetric edge removal,  $op_3$ –pairwise edge removal).

The sixth and seventh row shows the results for SMECN with  $c = 0$  and  $c = 20$ . The performance numbers of SMECN with  $c = 0$  in Table 1 are similar to those of OPT-CBTC. performance of SMECN degrades as the receive power increases. Moreover, SMECN requires GPS information, while CBTC requires only directional information. The last row in Table 1 gives the performance numbers for the case when topology control is absent under the assumption that each node uses the maximum transmission power

of  $p(250)$ . We can see that using topology control cuts down the average degree by a factor of more than 3 (3.8 vs. 15.0) and the average radius by a factor of more than 2 (113.1 or 110.7 vs. 250). Clearly, this is a significant improvement. Although OPT-CBTC reduces the power demand of nodes (average radius 115.1) as much as SMECN does (average radius 118.1), it is not necessarily always better to use OPT-CBTC, since SMECN preserves the minimum-energy path while OPT-CBTC does not. If a different power level can be used for each neighbor, and the amount of unicast traffic is significantly greater than the amount of neighbor broadcast traffic, using SMECN can be beneficial.

### 5.3 Network Performance Analysis

As Table 1 shows, the network graphs resulting from using CBTC with  $\alpha = 5\pi/6$  and  $\alpha = 2\pi/3$  are quite similar in terms of average node degree and radius. Thus, we consider only the case  $\alpha = 2\pi/3$  in our experiments.<sup>3</sup> To measure the performance of CBTC, SMECN, and MaxPower, we simulate these approaches using the same traffic pattern and random networks. Since the power available to a node is decreased after each packet reception or transmission, nodes in the simulation die over time. After a node dies, the network must be reconfigured. In our simulation, the NDP triggers the reconfiguration protocol. The NDP beacon for SMECN and CBTC is sent with a period of 1 second. The beacon uses power  $p(rad_{u,2\pi/3}^-)$  for CBTC and OPT-CBTC. For SMECN, the beacon uses the appropriate power level as computed by SMECN’s neighbor discovery process. For simplicity, we do not simulate node mobility, although some of the effects of mobility—that is, the triggering of the reconfiguration protocol—can already be observed when nodes run out of energy. The beacons are sent once per second. (The beacon is jittered randomly before it is actually sent to avoid synchronization effects.) Note that no beacon is required in the MaxPower approach. For the rest of this section, we first compare the performance of CBTC, SMECN, and MaxPower when the radio receiver power consumption is 0. Then we vary the receiver power to study its effect on the relative performance of the three approaches. Note that, our results are averaged over the 20 random networks described in Section 5.1.

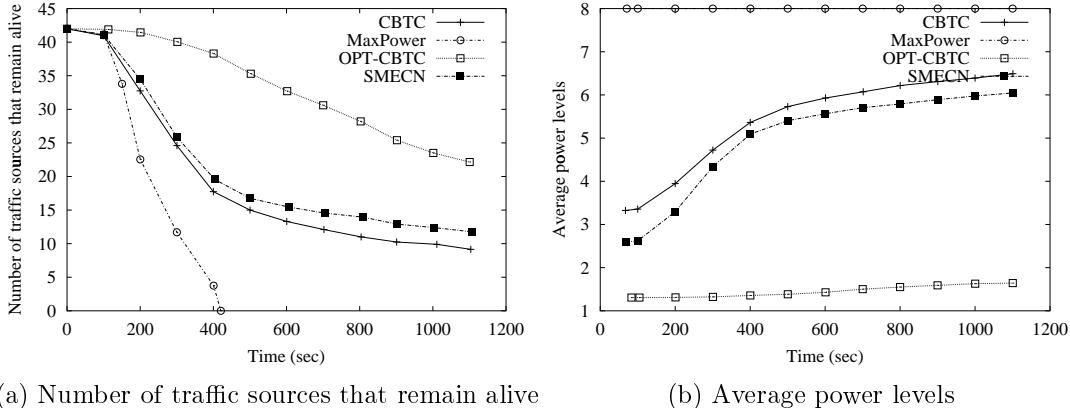

#### 5.3.1 Performance Comparison with Receiver Power $c = 0$

First, we investigate the performance of the three approaches assuming that the radio receiver consumes zero power when receiving. As can be seen from Figure 7, OPT-CBTC has the best performance. CBTC performs slightly worse than the SMECN algorithm, but uses only directional information. MaxPower has significantly worse performance than the other algorithms. Figure 7(a) shows the number of traffic sources that remain alive over time. We can see that when 72% of the traffic sources in MaxPower are dead at time 300, about 60% of the traffic sources are still alive in both CBTC and SMECN,

---

<sup>3</sup>Since we use only a few discrete power levels, there is no significant benefit in using  $\alpha = 5\pi/6$ .

and more than 95% of the traffic sources are still alive in OPT-CBTC. The basic CBTC algorithm does not perform as well as OPT-CBTC, but it still performs much better than MaxPower and has about the same performance as SMECN. Next, consider how

(a) Number of traffic sources that remain alive

(b) Average power levels

Figure 7: Performance comparison of different algorithms with  $c = 0\text{mW}$ .

the transmission power evolves over time as nodes die over time. Figure 7(b) shows the average power level averaged over all nodes. The “average power level” at time  $t$  is computed by considering, for each node  $u$  still alive at time  $t$ , the minimum power currently needed to for  $u$  to reach all its neighbors (recall that this is the power that  $u$  uses in the simulation to sending a point-to-point message), and then averaging this quantity over all nodes still alive at time  $t$ . This gives a good indication of the power level needed at time  $t$ . For MaxPower, the average power is constant over time, since maximum power is always used. For the other algorithms, it increases over time. What is perhaps most interesting is how little it increases in the case of OPT-CBTC. As we can see, the average power level to reach all neighbors in the case of CBTC and SMECN increases rapidly over time as more nodes die. The average power level needed to reach all neighbors in the case of OPT-CBTC increases rather slowly and is much smaller than that needed in the case of CBTC and SMECN.

We collected packet delivery and latency statistics at the end of our simulation. SMECN, CBTC and OPT-CBTC are able to deliver 1.74, 1.91, and 3.32 times the amount of packets delivered by MaxPower respectively, throughout the simulation. The statistics for packet delivery and number of traffic sources still alive show that it is undesirable to transmit with large radius, since it increases energy consumption and causes unnecessary interference, and consequently decreases throughput. It is interesting to note that MaxPower and OPT-CBTC have similar latency (OPT-CBTC is about 8% higher), as do CBTC and SMECN (CBTC is about 10% higher). However, the latency MaxPower and OPT-CBTC is about three times that of CBTC and SMECN. OPT-CBTC has higher latency because it typically take longer routes due to using lower transmission

power. MaxPower has higher latency due to its low spatial reuse of the spectrum. That is, a successful transmission by MaxPower reserves a large physical area. Any node that hears the transmission within this area backs off and does not transmit itself. Therefore, the larger the area reserved, the fewer nodes can transmit at any particular time. Since a transmission by CBTC reserves a much smaller area, many nodes can transmit at the same time.

### 5.3.2 Varying the Receiver Power

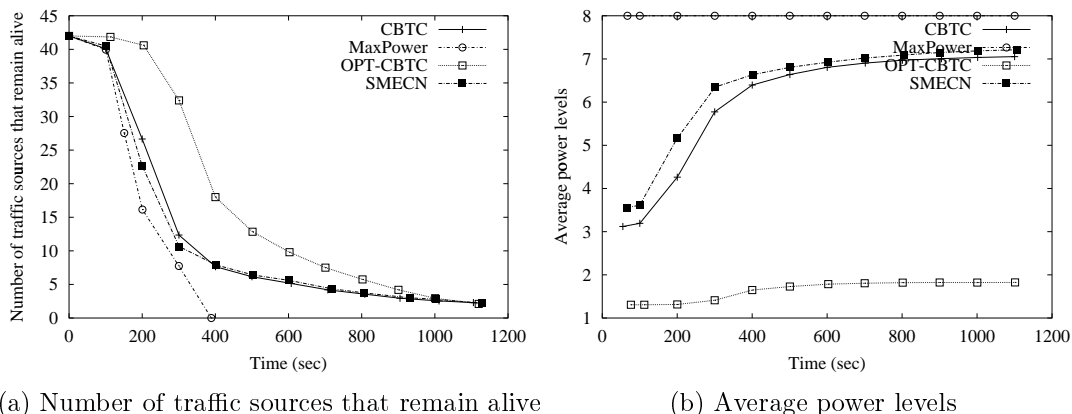

Figure 8: Performance comparison of different algorithms with  $c = 20\text{mW}$ .

We now consider what happens if the receiver consumes  $20\text{mW}$  of power when receiving a message. As Figure 8(a) shows, in this case, the number of traffic sources alive decreases much more quickly than in the case of  $c = 0$ . For instance, at time 400 when all the sources for MaxPower have just died in both cases, there are only 7, 7, and 18 sources alive for CBTC, SMECN and OPT-CBTC, respectively, if  $c = 20$ , while if  $c = 0$ , there are 17, 19, and 38 sources alive, respectively. MaxPower is not affected by the change in receiver power because it does not use periodic NDP beacons, while the other algorithms do (and thus, nodes running one of the other algorithms must expend power to receive these periodic beacons). Not surprisingly, the performance improvements of the topology-control algorithms over MaxPower is smaller in the case of  $c = 20$  than in the case of  $c = 0$ . For instance, SMECN, CBTC and OPT-CBTC deliver only 1.30, 1.19, and 1.78 times the number of packets delivered by MaxPower, respectively, throughout the simulation. The latency of the topology-control algorithms is also relatively worse if  $c = 20$  than if  $c = 0$ , since longer routes end up being used more earlier.

We remark that the assumption that MaxPower does not use NDP may not apply in practice, since many protocols depend on it. Thus, the performance improvements of topology control over MaxPower presented here represents rather conservative estimates.

## 6 Conclusion

We have analyzed the distributed cone-based algorithm and proved that  $5\pi/6$  is a tight upper bound on the cone degree for the algorithm to preserve connectivity. We have also presented three optimizations to the basic algorithm—the shrink-back operation, asymmetric edge removal, and pairwise edge removal—and proved that they improve performance while still preserving connectivity. Finally, we showed that there is a tradeoff between using CBTC( $\alpha$ ) with  $\alpha = 5\pi/6$  and  $\alpha = 2\pi/3$ , since using  $\alpha = 2\pi/3$  allows an additional optimization, which can have a significant impact on reducing the transmission radius. The algorithm extends easily to deal with reconfiguration and asynchrony. Most importantly, simulation results show that it is very effective in reducing power demands and increases the overall throughput.

Since the focus of this paper has been on reducing energy consumption, we conclude with some discussion of this goal. Reducing energy consumption has been viewed as perhaps the most important design metric for topology control. There are two standard approaches to doing this: (1) reducing the transmission power of each node as much as possible; (2) reducing the total energy consumption through the preservation of minimum-energy paths in the underlying network. These two approaches may conflict: reducing the transmission power required by each node may not result in minimum-energy paths or vice versa. Furthermore, there are other metrics to consider, such as network throughput and network lifetime. Reducing energy consumption tends to increase network lifetime. (This is particularly true if the main reason that nodes die is loss of battery power.) However, there is no guarantee that it will. For example, using minimum-energy paths for all communication may result in hot spots and congestion, which in turn may drain battery power and lead to network partition. Using approach (1) in this case may do better. If topology control is not done carefully, network throughput can be hurt. As we have already pointed out, eliminating edges may result in more congestion and hence worse throughput, even if it saves power in the short run. The right tradeoffs to make are very much application dependent. We hope to explore these issues in more details in future work.

## A Proof for Theorem 2.1

**Fact A.1** *The distance  $d$  between any two points  $u, v$  in a  $\beta < \pi/3$  sector of a circle is no greater than the circle radius  $r$ . If both  $u$  and  $v$  are not the center of the circle, then  $d < r$ .*

**Lemma A.2** *In Figure 9,  $\text{circ}(z, d)$  intersects  $\text{circ}(v, d)$  on the arc from  $u$  clockwise to  $q$  at point  $t$ .*

**Proof:** For any two points  $t', t''$  on the arc from  $u$  clockwise to  $q$ , if  $\angle t'vz > \angle t''vz$ , then  $d(t', z) > d(t'', z)$ . This follows from a simple geometry argument. Consider triangles  $\triangle t'vz$  and  $\triangle t''vz$ . Since  $d(t', v) = d(t'', v) = d$  and the triangles have one side  $vz$  in common,  $\angle t'vz > \angle t''vz$  implies  $d(t', z) > d(t'', z)$ . Since  $d(u, z) \geq d$  (by assumption) and  $d(q, z) < d$  (by Fact A.1), there must be a point  $t$  on the arc from  $u$  clockwise to  $q$  such that  $d(t, z) = d$ . ■
